Submitted 24 September 2015; accepted in final form 2 December 2015

FOR NEARLY TWENTY-FIVE YEARS, investigators have employed acute transverse slice preparations containing the preBötzinger complex (preBöC) to probe the cellular and synaptic bases for respiratory rhythm generation in rodents (Feldman et al. 2013; Funk and Greer 2013; Smith et al. 1991). These “breathing slice” preparations retain sufficient circuitry from the ventrolateral brainstem displayed up to 193% faster burst frequency (22.4 ± 8.3 bursts/min) and higher signal amplitude (340%) compared with acute slices. We conclude that preBöC-containing slice cultures retain inspiratory-like rhythmic function and therefore may facilitate lines of experimentation that involve extended incubation (e.g., genetic transfection or chronic drug exposure) while simultaneously being amenable to imaging and electrophysiology at cellular, synaptic, and network levels.

preBötzinger complex; breathing; respiration; central pattern generator; organotypic slice cultures; rhythmogenesis; rhythm generation

MATERIALS AND METHODS

Ethical approval. The Department of Experimental Medicine at the Panum Institute approved all experiments and procedures according to protocols laid out by Danish Ministry of Justice and the Danish National Committee for Ethics in Animal Research.

1063-1070, 2016. First published December 9, 2015; doi:10.1152/jn.00904.2015.—Study of acute brain stem slice preparations in vitro has advanced our understanding of the cellular and synaptic mechanisms of respiratory rhythm generation, but their inherent limitations preclude long-term manipulation and recording experiments. In the current study, we have developed an organotypic slice culture preparation containing the preBötzinger complex (preBöC), the core inspiratory rhythm generator of the ventrolateral brain stem. We measured bilateral synchronous network oscillations, using calcium-sensitive fluorescent dyes, in both ventrolateral (presumably the preBöC) and dorsomedial regions of slice cultures at 7–43 days in vitro. These calcium oscillations appear to be driven by periodic bursts of inspiratory neuronal activity, because whole cell recordings from ventrolateral neurons in culture revealed inspiratory-like drive potentials, and no oscillatory activity was detected from glial fibrillary associated protein-expressing astrocytes in cultures. Acute slices showed a burst frequency of 10.9 ± 4.2 bursts/min, which was not different from that of brain stem slice cultures (13.7 ± 10.6 bursts/min). However, slice cocultures that include two cerebellar explants placed along the dorsolateral border of the brainstem displayed up to 193% faster burst frequency (22.4 ± 8.3 bursts/min) and higher signal amplitude (340%) compared with acute slices. We conclude that preBöC-containing slice cultures retain inspiratory-like rhythmic function and therefore may facilitate lines of experimentation that involve extended incubation (e.g., genetic transfection or chronic drug exposure) while simultaneously being amenable to imaging and electrophysiology at cellular, synaptic, and network levels.

However, acute slices remain viable and rhythmically active for ~1 day (Funk and Greer 2013), which limits the scope of techniques that may be applied. Pharmacological assays are limited to time windows of several hours, which prohibit studies of chronic drug effects on respiratory network function. Furthermore, experiments that involve genetic manipulation or transfection require several days for protein expression and thus are impossible to perform using acute slices. It would therefore be advantageous to have an in vitro preparation that retains a functional preBöC for days or weeks, and facilitates genetic and pharmacological manipulation while retaining behaviorally relevant network activity that can be monitored and recorded with the ease offered by acute slices.

With the use of organotypic culturing techniques, partial slice preparations of the preBöC have been successfully maintained over multiweek periods (Hartelt et al. 2008). These slice cultures, cut 250 μm thick, preserve some rhythmic function but contain only a fraction of the preBöC neurons normally captured in 400- to 700-μm-thick breathing slices (Funk and Greer 2013). Hartelt et al. recorded rhythmic low-frequency action potential bursts in some cells but did not analyze whether coordinated patterns of network activity were generated in their cultures. Thus a culture preparation that retains the preBöC rhythmic core bilaterally, throughout its anterior-posterior extent, which typifies acute rhythmically active slice preparations, has not yet been described.

In this article we present a novel slice preparation that retains the preBöC bilaterally using both the Stoppini membrane method and the Gähwiler roller-drum method of organotypic slice culturing (Gahwiler 1981; Stoppini et al. 1991). This new culture preparation generates synchronized network activity bilaterally in the ventrolateral, preBöC-related regions of the slice, analogous to rhythms in acute slice preparations. The preparation shows spontaneous rhythm over several weeks of culturing and flattens out, which improves the quality of optical imaging at the cellular and network level. Furthermore the neurons are accessible for whole cell patch clamping, meaning that both network activity and individual neurons can be selectively recorded from and perturbed using methods already established in the acute slice preparation.
Organotypic slice cultures. U.S. Naval Medical Research Institute (NMRI) mice postnatal ages 0.5–5.5 days were anesthetized with isoflurane and immediately dissected in sterile-filtered chilled artificial cerebrospinal fluid (ACSF) containing (in mM) 184 glycerol, 2.5 KCl, 1.2 NaH2PO4, 30 NaHCO3, 20 HEPES, 25 d-glucose, 5 sodium ascorbate, 2 thioura, 3 sodium pyruvate, 10 MgSO4, and 0.5 CaCl2; pH 7.3, equilibrated by bubbling with carbogen (95% O2 and 5% CO2). We cut transverse slices of the brain stem, 400 μm in thickness, at the level of the preBötzinger on a vibratome (Thermo Scientific Microm 650V; Waltham, MA) as described by newborn mouse atlases of the brain stem (Ruangkittisakul et al. 2011, 2014). Additionally, we often retained 400-μm-thick parasagittal slices of the cerebellum from the same mouse brain for co-culturing. For Stoppini-type cultures, transverse brain stem slices were placed onto semiporous culture well inserts (Millipore PICO3050; Darmstadt, Germany) with cerebellar explants cocultured along their dorsolateral borders. Mounted preparations were maintained in sterile-filtered organotypic culture medium containing 50% Eagle’s MEM with Earle’s salts, 25% Hank’s balanced salt solution, 25% heat-inactivated horse serum, 2 mM d-glucose. The cultures were treated with 3-EMBed-812; Electron Microscopy Sciences, Hatfield, PA), cut in buffer (0.1 M), dehydrated with increasing ethanol, embedded in Epon, and an additional 3.6 mM D-glucose. The cultures were treated with 10 μM MK-801, an NMDA receptor antagonist, for the first 3 days in vitro. Fresh culture medium was supplied every 48 h thereafter until experimentation. These slices were then kept in a sterile humidified incubator at 35°C and atmospheric CO2 concentrations during incubation.

We prepared some cultures according to the roller-drum technique, wherein the slices were placed on a coverslip embedded in citrated chicken plasma (Sigma-Aldrich, St. Louis, MO) that was then coagulated by adding a drop of 100–150 U/μl thrombin (Sigma-Aldrich). The cultures were kept in sealed plastic tubes (flat bottom; NUNC, Denmark, Homburg, Germany) (Lalo et al. 2006). Change in fluorescence over baseline fluorescence (Leica GFP3; excitation bandpass 450–490 nm and emission bandpass 500–575 nm) were inserted in the light path for fluorescence imaging. Time series acquisition was performed with an electron-multiplying charge-coupled device camera (LucaEM S DL-658M; Andor Technology, Belfast, UK) at 10–12 Hz, controlled by SOLIS software (Andor Technology).

For cellular level fluorescence detection, a metal halide light source (PhotoFluor II; 89 North, Burlington, VT) or an LED light source (M470L2; Thorlabs, Newton, NJ) was coupled to a fixed-stage upright microscope via a liquid light guide and appropriate optical filters (for fluo-8 AM, a modified Olympus U-MWIB set: excitation 457–487 nm, dichroic mirror 520–550 nm, emission 515–550 nm; for Asante calcium red AM, a modified Olympus U-MWIG2 set: excitation 520–550 nm, dichroic mirror 565 nm, emission BAS800IF nm). Images were captured by an sCMOS camera (Neo DC-152Q; Andor Technology) controlled by the SOLIS software (Andor Technology). Imaging protocols employed ×10 (NA 0.3), ×20 (NA 0.5), ×40 (NA 0.8), and ×63 (NA 0.95) water-immersion objectives. Time series images were acquired at 10–50 frames/s.

The NK1-receptor agonist substance P acetate salt hydrate (SP) and μ-opioid agonist [d-Ala2, N-Me-Phe4, Gly5-ol]-enkephalin acetate salt (DAMGO; Sigma-Aldrich) were dissolved in water and further diluted in ACSF to give final concentrations of 500 nM and 1 μM, respectively. The effect of SP and DAMGO on burst frequency was tested in cumulative dosing measuring burst frequency over 20-s intervals in the continuous presence of 1.5 ml of a standard ACSF containing 10 μM MK-571 (an ATP-binding cassette transporter blocker that improves calcium indicator dye uptake; Manzini et al. 2008). The ACSF consisted of (in mM) 129 NaCl, 3 KCl, 25 NaHCO3, 5 KH2PO4, 30 d-glucose, 0.7 CaCl2, 0.4 MgSO4, 100 mM d-mannitol, which was aerated with carbogen (95% O2 and 5% CO2) at room temperature. The final fluo-8 AM (or Asante calcium red) concentration was 20 μM. Slice cultures were submerged in bubbled loading solution for 30–60 min before recording began.

Fluorescent calcium activity was recorded in the slice culture using a stereo microscope (Leica MZ16 FA; Wetzlar, Germany) 30 min after the preparation was placed in a 2-ml recording chamber at 29°C and perfused at 2 ml/min with preheated oxygenated ACSF. Light-emitting diodes (LEDs; HLV series; CCS LED Spotlight, Kyoto, Japan) and a metal-halide light source (Leica EL6000) illuminated the preparation. Appropriate filter sets for green fluorescence (Leica GFP3; excitation bandpass 450–490 nm and emission bandpass 500–575 nm) were inserted in the light path for fluorescence imaging. The thickness of the cultures was measured in counterstained sections using a Zeiss Axiolab microscope. The culture was drop fixed with 4% paraformaldehyde, washed in Sørensen’s phosphate buffer (0.1 M), dehydrated with increasing ethanol, and placed in a rotating roller drum (15 revolutions/h) at 35°C in humidified air. All procedures were performed in a sterile work environment within a Class I biosafety cabinet. The success rate in obtaining oscillating cultures depended in particular on the dissection experience and skill of experimenter, and approached 100% after ~3 mo of training.

Electroporation. Glass micropipettes were pulled from filamented capillary glass (outer diameter 1.5 mm, inner diameter 0.86 mm; Harvard Apparatus, Holliston, MA) using a PUL-100 micropipette puller (World Precision Instruments, Sarasota, FL), giving a tip diameter of 1–3 μm. Pipettes were filled with 1% biocytin, 1 M KCl, and 0.126 M Tris, which were placed in the slice culture, and positive current was applied in 50-ms pulses of 200 μA at 2 Hz for 10 min.

Current pulses were generated by a stimulus isolation unit (SIU-1; WPI, Sarasota, FL) and amplified by a 2B amplifier (Molecular Devices, Sunnyvale, CA) and ROE-200 micromanipulators (Sutter Instruments, Novato, CA). Glass patch pipettes were pulled as described above to a tip resistance of 9–11 MΩ. Pipettes were loaded with a patch solution containing (in mM) 165 potassium d-glucurate, 10 NaCl, 0.5 MgCl2, 10 HEPES, 0.4 GTP, 4 ATP, and 0.5 EGTA, pH 7.3, and then visually guided to target cells using a fixed-stage upright microscope (modified Olympus BX51) with a ×63 (NA 0.95) objective. Data were digitally acquired at 20 kHz. Rhythmically active neurons were first recorded with the minimum necessary current bias to achieve stable activity with little spontaneous firing during interburst intervals.

Analysis and statistics. Optical and electrophysiological data were analyzed offline using Igor Pro v. 6.36 (WaveMetrics, Lake Oswego, OR), Clampex 10.3 (Molecular Devices), and ImageJ v. 1.49 (Schneider et al. 2012). Changes in fluorescence over baseline fluorescence intensity (ΔF/ΔF0) was calculated using a moving Z-projection that finds minimum values of fluorescence across consecutive 1-s time windows throughout an image stack. The 1-s running average, uniquely calculated for each individual frame, was subtracted from it throughout the time series to isolate fast calcium fluctuations from background fluorescence. Image stacks were then Kalman filtered to reduce noise and pseudocolored (“rainbow” RGB look-up table: red, maximum values of ΔF; green, medium values of ΔF; blue, minimum...
values of $\Delta F$). Pixels were binned (mean of adjacent $2 \times 2 - 10 \times 10$ points) and brightness and contrast were enhanced using ImageJ. In some experiments, regions of interest (ROIs) were defined and average $\Delta F$ values within a given ROI were plotted versus time. Unless otherwise stated, statistical values are means ± SD. Student’s t-test was used for statistical comparisons of two sample populations, and ANOVA was used when more than two sample populations are compared. All statistical tests were performed using Origin 2015 (OriginLab, Northampton, MA).

RESULTS

Oscillatory activity in acute slices, brain stem slice cultures, and brain stem-cerebellar cocultures. Bilateral oscillatory calcium activity was detected in fluo-8 AM-loaded brain stem slices that expose the preBöTc at their rostral surface (Ruangkittisakul et al. 2011, 2014) and was subsequently imaged both acutely and after 7–28 days in vitro (DIV) using the Stoppani culturing method (Fig. 1, A and B). In both acute slices and cultures, synchronized calcium activity was observed in an inverted V-shaped pattern with signals concentrated in dorsal (Fig. 1, A and B, blue circles) and ventral oscillatory groups (Fig. 1, A and B, red circles). Acute slices showed respiratory-related rhythmic activity at 10.9 ± 4.2 bursts/min ($n = 10$), and slices maintained in organotypic culture for 7–22 DIV oscillated at 13.7 ± 10.6 bursts/min ($n = 15$). When we cocultured the brain stem slice with two cerebellar slice explants (placed along either the dorsolateral or ventrolateral border of the slice), then the rhythm was faster (22.4 ± 8.3 bursts/min, $n = 26$; Fig. 1, C and D; Supplemental Video S1, available in the data supplement online at the Journal of Neurophysiology Web site). Brain stem-cerebellar cocultures (7–43 DIV) were faster than both acute slices and brain stem slice cultures, and there was no significant linear correlation or other obvious relationship between DIV and burst frequency (not shown; linear correlation coefficient $r = 0.1$, $n = 19$). Preparation type had a significant effect on frequency [$F(2,48) = 8.9$, $P = 0.0005$; Fig. 1D, left]. Post hoc comparison using Bonferroni or Tukey tests indicate that coculture oscillation frequency is significantly different from that in brain stem slice cultures (mean difference = 8.7 bursts/min, $P = 0.008$) and acute slices (mean difference = 11.5 bursts/min, $P = 0.002$).

Calcium transients in brain stem slice cultures were longer lasting and had a slower onset compared with acute slices or brain stem-cerebellar cocultures. The mean burst duration of calcium activity in the ventral oscillatory group of brain stem slice cultures measured 785 ± 257 ms ($n = 13$) compared with 367 ± 59 ms in acute slice preparations ($n = 10$) and 514 ± 169 ms in cocultures ($n = 26$). Preparation type had a significant effect on burst duration [$F(2,46) = 16.2$, $P = 4.7 \times 10^{-5}$; Fig. 1D, middle]. Post hoc comparison tests indicate that brain stem slice culture burst duration is significantly different from that in both acute slices (mean difference = 418 ms, $P = 6.1 \times 10^{-5}$) and cocultures (mean difference = 272 ms, $P = 0.0002$).

The rate of signal onset, measured as the 10–90% rise time above baseline fluorescence, was slower in brain stem slice cultures (375 ± 213 ms, $n = 13$) compared with acute slice preparations (226 ± 43 ms, $n = 10$) and cocultures (223 ± 57 ms, $n = 26$). Preparation type had a significant effect on signal onset [$F(2,46) = 7.8$, $P = 0.001$; Fig. 1D, right], and post hoc comparison tests indicate that burst rise time in brain stem slice culture is significantly different from that in both acute slices (mean difference = 149 ms, $P = 0.01$) and cocultures (mean difference = 152 ms, $P = 0.001$).

The signal-to-noise ratio was higher in cocultured preparations compared with acute slices. Under similar dye-loading...
Innovative Methodology

SLICE CULTURES OF THE preBÖTZINGER COMPLEX

and imaging conditions, peak calcium signals from the center of the ventral oscillatory group measured 340% higher in magnitude in cocultured preparations (5.5 ± 3.3%, n = 8) and 550% higher in brain stem slice culture preparations (8.8 ± 3.1%, n = 8) compared with acute preparations [1.6 ± 0.7%, n = 8; F(2,21) = 14.8, P = 9.6 × 10^{-3}]. Active areas whose calcium activity was not normally visible in acute slices also became apparent in cultured preparations. In 53% (n = 34) of all cultured preparations, midline activity between ventral oscillatory groups was detectable.

We also prepared brain stem slices cocultured with cerebellar explants using roller-drum methods (Gahwiler 1981), and these cultures (17–19 DIV) also showed spontaneous oscillatory activity, with a burst frequency of 28.6 ± 5.9 bursts/min, burst duration of 625 ± 97 ms, and 10–90% rise time of 269 ± 29 ms. These characteristic measurements were not significantly different from those of similar Stoppini-type co-cultures (P = 0.09–0.16, n = 5).

Spread of activity in brain stem slice cultures and brain stem-cerebellar cocultures. Both brain stem slice cultures and brain stem-cerebellar cocultures display oscillatory calcium burst patterns that propagate ipsilaterally, traveling from their point of initiation in the ventrolateral area toward the dorsomedial border at varying velocities (Fig. 2A). When imaged at 129 Hz, the signal in brain stem-cerebellar cocultures propagated 275% as fast (0.022 ± 0.007 m/s, n = 8) as that in brain stem slice cultures (0.008 ± 0.005 m/s, n = 9, P < 0.001; Fig. 2B). In each slice there was a detectable latency in the signal rise between contralateral ventral oscillatory groups. In every case, for both brain stem slice cultures and brain stem-cerebellar cocultures, calcium signals took longer to propagate from ventral to dorsal regions than to contralaterally equivalent regions, where the activity appeared within 1–2 frames, which made it too uncertain to calculate a precise velocity or possible dominant or alternating initiation site (n = 7). Thus, regardless of preparation type, synchronized bursts first occurred bilaterally between contralateral ventral oscillatory groups and then propagated more slowly in the dorsomedial direction.

Ventral oscillatory group activity in multiple neurons and calcium transients in dendritic profiles. In acute slice preparations, calcium and voltage dye fluorescence imaging often appears as diffuse regional fluorescence due to light scattering in the tissue, or instead captures only a subset of rhythmically active neurons within the field of view or focal plane (Funk and Greer 2013; Koshiya and Smith 1999; Koshiya et al. 2014; Onimaru and Homma 2003). Similarly, live imaging of dendritic processes at the cellular level, even with the aid of two-photon and confocal imaging, can be difficult due to branching in the Z-axis and increased light scattering at locations deep within the slice (Del Negro et al. 2011; Funk and Greer 2013; Katona et al. 2011). One advantage of culturing brain slices is the reduced thickness compared with acute slices (Stoppini et al. 1991). Using the Stoppini culturing method, we reduced the thickness of the brain stem slices cultured to 104 ± 31 μm (measured in sagittal sections of Epon-embedded 7–31 DIV oscillating cultures, n = 5) from a thickness of 400 μm in the acute slices at 0 DIV. The dorsal-to-ventral distance at the slice midline increased to 1,943 ± 183 μm compared with 1,490 ± 74 μm in acute slices acquired from age-matched controls (postnatal day 2.5; P < 0.05, n = 5). Thus the cultures flatten out and the reduced thickness made it possible to record synchronized calcium transients from hundreds of neurons in the same focal plane (Fig. 3, A and B). At higher magnification, both somatic and proximal (∼100 μm) dendritic activity could be recorded in fluo-8 AM-loaded neurons (Fig. 3C; Supplementary Video S2).

Retrograde biocytin labeling in roller-drum cultures. The preBöC contains commissural interneurons, which synchronize bilateral halves of the preBöC, as well as interneurons that project ipsilaterally to premotor neurons in the intermediate reticular formation as well as hypoglossal motor neuron pools (Wang et al. 2014). If the inverted V-shaped pattern of rhythmic calcium activity in cultures corresponds to that seen in acute slices, then similar axon projections ought to be

Fig. 2. Propagation of calcium activity in brain stem slice cultures and brain stem-cerebellar cocultures. A: time series Z projection of maximum fluorescent calcium activity in a brain stem-cerebellar coculture. The heat map overlay shows threshold signal increases from low (red) to high latencies (blue) during a single rhythmic burst acquired at 129 frames/s. B: average velocity of signal propagation in BC vs. CC preparations. Error bars indicate means ± SE. **P < 0.001 (Student’s t-test).

Fig. 3. Low- and high-magnification views of oscillatory activity. A, left: oscillatory calcium activity in the ventral oscillatory group at low magnification using ×10 objective (Z projection of standard deviation from 200-frame image stack at 10 Hz; V, ventral; M, medial). Right, position of 200 oscillating cell body ROIs from the image at left. B: waterfall diagram of ΔF/F0 traces from the 200 ROIs shown in A. Note the tight synchronization during 2 cycles. C, left: cycle-triggered average of oscillatory calcium activity at high magnification using a ×63 objective. Note the visualization of somas and dendritic profiles. Right, reconstruction of the soma-dendritic territory from 1 neuron and the associated ΔF/F0 traces from 3 dendritic and 1 somatic ROI (indicated by dotted squares).
maintained in the cultured preparation. To test this prediction, we electroporated 1% biocytin using patch pipettes placed in the ventral oscillatory group of Roller-drum cultures (n = 3). Retrogradely labeled neurons were located around the injection site; somata and projecting fibers were found in the ipsilateral dorsal part of the culture, at the midline, and in the contralateral ventrolateral part of the cultures (Fig. 4, A and B). The biocytin labeling suggests that the pattern of activity in cultures is attributable to an underlying bilateral network of neurons in the preBötC, which also project dorsally, presumably to premotor and motor-related respiratory neural circuits. Biocytin-labeled fibers entering the cerebellar explant, terminating in bouton-like structures, were detected in one slice coculture (Fig. 4, B and D), indicating a degree of synaptic interconnectivity between the brain stem and cerebellar neurons.

**Calcium activity in GFAP-labeled cells.** Oscillatory calcium transients have been reported in astrocytes in sync with neighboring preBötC neurons (Oku et al. 2015). We tested for rhythmic glial activity in brain stem-cerebellar cocultures prepared from transgenic mice that express EGFP coupled to rhythmic glial activity in brain stem-cerebellar cocultures prepared from transgenic mice that express EGFP coupled to rhythmic activity in cultures is attributable to an underlying bilateral network of neurons in the preBötC, which also project dorsally, presumably to premotor and motor-related respiratory neural circuits. Biocytin-labeled fibers entering the cerebellar explant, terminating in bouton-like structures, were detected in one slice coculture (Fig. 4, B and D), indicating a degree of synaptic interconnectivity between the brain stem and cerebellar neurons.

**Calcium activity in GFAP-labeled cells.** Oscillatory calcium transients have been reported in astrocytes in sync with neighboring preBötC neurons (Oku et al. 2015). We tested for rhythmic glial activity in brain stem-cerebellar cocultures prepared from transgenic mice that express EGFP coupled to rhythmic glial activity in brain stem-cerebellar cocultures prepared from transgenic mice that express EGFP coupled to rhythmic activity in cultures is attributable to an underlying bilateral network of neurons in the preBötC, which also project dorsally, presumably to premotor and motor-related respiratory neural circuits. Biocytin-labeled fibers entering the cerebellar explant, terminating in bouton-like structures, were detected in one slice coculture (Fig. 4, B and D), indicating a degree of synaptic interconnectivity between the brain stem and cerebellar neurons.

**Whole cell electrophysiology.** To assess whether neuronal behavior in cultures resembles preBötC neurons in acute slice preparations (Funk and Greer 2013), we recorded the voltage trajectory in rhythmic neurons from culture preparations. First, using calcium imaging, rhythmically active cells within the ventral oscillatory group were targeted for whole cell patchclamp recordings (Fig. 6A; n = 10). Rhythmic drive potentials (duration 343 ± 207 ms, n = 7) that reflect underlying network activity were recorded at typical membrane potential (overriding action potentials were removed via bandpass filtering) and at hyperpolarized potentials by using negative bias current to uncover nonlinear membrane behavior indicative of recruitment of active conductances (Fig. 6B). The amplitude of the underlying drive potential was 185% larger in rhythmic neurons held at close to resting membrane potential (19.0 ± 6.6 mV; n = 7) than in neurons held at membrane potentials below the threshold of action potential generation during the burst (10.3 ± 3.7 mV; n = 5, P < 0.05).

Finally, we tested pharmacological modulation of burst frequency by neuropeptides. From a control frequency of 24.4 ± 6.4 bursts/min, the NK1-receptor agonist SP (500 nM) sped up the frequency by 134% to 32.7 ± 9.3 bursts/min (P < 0.05), and adding the µ-opioid agonist DAMGO (1 µM) on top of SP slowed the frequency by 50% to 16.5 ± 8.7 bursts/min (P < 0.01, n = 6 cumulative dosings; Fig. 6C).
by local synaptic processes in networks of neurons. The pattern also overlaps the expression of cells, in the transverse plane of the brain stem and cervical spinal cord, derived from the homeodomain transcription factor Dbx1, which gives rise to rhythmonic interneurons that comprise the preBötC (Bouvier et al. 2010; Gray et al. 2010; Picardo et al. 2013) and also play a role in premotor drive transmission (Wang et al. 2014).

In some recordings we also observed midline activity, which may reflect raphe neurons that interconnect with the preBötC and increase firing frequency in response to rhythmic preBötC input (Ptak et al. 2009). Retrograde biocytin labeling from the ventral oscillatory group revealed projections in both the contralateral ventral oscillatory group and dorsomedial regions, similar to that obtained via in vivo fluoro gold injection into the preBötC (Koshiya et al. 2014). Retrogradely labeled neurons were also found in the midline, further suggesting the involvement of raphe neurons. Thus it appears unlikely that rhythm calcium changes in the slice occur due to spontaneous calcium oscillations, but rather they resemble the neuronal behavior found in acute slices, similar in both dynamics and patterning, and occurring over anatomic regions that correspond to known areas of activity and to locations of cells vital for production of the respiratory rhythm. The presence of cerebellar explants cocultured with preBötC slices bolsters the rhythm, causing it to oscillate faster than acute preBötC preparations, but with similar burst duration and 10–90% rise times. Without the addition of cerebellar explants, brain stem cultures oscillate at the same frequency as acute preparations, but individual bursts have a slower onset and offset: increased burst duration and rise time. Although the specific roles of cerebellar explants that promote preBötC-like rhythmic activity in cultures are unknown, spontaneous oscillatory activity in cerebellar granule cells may contribute to the overall excitability of the slice (Apuschkin et al. 2013; De Zeeuw et al. 2008), especially if coculturing allows granule cell axon entry into the preBötC and facilitates excitatory synaptic connections with preBötC interneurons of the ventral oscillatory group. Since preBötC-like rhythmic behavior occurred in the absence of cerebellar explants but these rhythms were faster with cerebellar cocultures, we conclude that cerebellar circuits augment excitability in the cultured preBötC but do not contribute to the cellular mechanisms underlying rhythm generation.

Because of gradual thinning of the slice and consequent reduction of light scattering in the tissue over time, the brain stem slice culture preparation allows for higher spatial resolution during imaging at both the cellular and network level and greater amplitude of fluorescent signals. This could be advantageous for analyzing larger portions of rhythmically active cell populations in the preBötC and adjacent premotor areas than has previously been possible in acute slices. For example, the culture preparation we characterize in this report may facilitate real-time visualization and perturbation of individual burst percolation across the rhythmogenic core and into premotor areas. Our preparation makes it feasible to stimulate and record large populations (approximately hundreds of neurons), since neighboring somata that would otherwise be spread through the Z-axis become coplanar (or nearly so for practical purposes). These conditions also simplify imaging requirements: population-level recordings could be acquired using wide-field excitation. Additionally, subcellular sections of neurons (e.g., dendritic processes) could be visualized at higher frequencies in the slice, which may contribute to the overall excitability of the slice.
Astrocytes have been implicated in respiratory rhythm generation (Hartel et al. 2009; Hulsmann et al. 2000; Oku et al. 2015; Schnell et al. 2011). We tested for the presence of calcium oscillations in the astrocytes of brain stem-cerebellar cocultures. We were able to image a large number of cells simultaneously using conventional wide-field illumination microscopy. We used a bath-applied red-shifted calcium indicator, despite an inherently reduced fluorescence intensity compared with brighter green dyes (e.g., Oregon green BAPTA 1, fluo 8), because of the flattened state and reduced tortuosity in the culture preparation. There was no apparent preinspiratory activity or oscillatory activity in 288 recorded GFAP+ cells. However, we cannot entirely rule out low-amplitude calcium oscillations. Previous recordings from astrocytes in preBötC brain stem slices employed the high-affinity indicator Oregon green BAPTA 1 (Kd = 170 nM), whereas we used the medium-affinity indicator Asante calcium red (Kd = 400 nM). Previously reported astrocytic fluctuations were of small amplitude (<1% ΔF/F0) and only visible after filtering (Oku et al. 2015). It is therefore plausible that we failed to detect astrocytic fluctuations due to experimental limitations related to our green GFAP reporter strain coupled with a red calcium dye of limited sensitivity. Furthermore, the tight proximity of cell layers in culture conveniently allows many cells to be recorded simultaneously with less light scattering due to tissue thickness, but the signal is likewise prone to contamination by neuronal activity that is marginally out of focus yet still of a greater magnitude than any glial signals, which may be especially true at higher magnification. Finally, it is possible that astrocytes in this case were inadequately labeled due to loading feasibility of the indicator dye or that they simply behaved differently in a culture environment.

Whole cell electrophysiology data show neurons in the ventral oscillatory group of brain stem-cerebellar cocultures whose behavior appears similar to previously described rhythmic neurons in the preBötC of acute slices (Funk and Greer 2013; Ramirez et al. 2012). These neurons receive periodic inspiratory drive potentials that generally produce bursts of action potentials with an underlying burst envelope that is larger at rest than at hyperpolarized potentials (Fig. 6B), suggesting that voltage- or calcium-dependent conductances amplify the synaptic drive (Ramirez et al. 2012). The drive potentials had a duration of ~350 ms, which compares to the ~870-ms half-amplitude duration of the calcium signal in individual neurons, illustrating that the shape and time course of the calcium signal also depend on cellular calcium kinetics. Taking these findings in conjunction with calcium imaging data and retrograde tracing with biocytin, we conclude that organotypic cultures retain a rhythmically active ventral network that corresponds to the preBötC. Its activity pattern spans dorsally into regions such as the intermediate reticular formation, the nucleus tractus solitarius, and the XII nucleus, which are associated with premotor and motor circuits that serve respiration. Midline activity also appears to correspond with the raphe obscurus (Ptak et al. 2009). Decreased tissue thickness, and consequently the ability to capture many active neurons in the same focal plane with significantly reduced fluorescence scattering, likely accounts for the increase in signal amplitude in cultures (both brain stem slice cultures and brain stem-cerebellar cocultures) compared with acute slices. However, the existence of rhythmic neurons in the ventrolateral slice culture, and in adjacent dorsomedial regions, does not necessarily guarantee that these neurons correspond one-to-one to preBötC interneurons and respiratory premotor or motor neurons, or that they have not modified their behavior or physiology in some way. A degree of synaptic remodeling certainly occurs over time in vitro: we can see promiscuous fibers projecting between cerebellar and brain stem explants via retrograde biocytin tracing. Thus we cannot exclude the possibility that circuits not found in the intact animal or unnatural strengthening of existing circuits develops over time in the cultures, which certainly should be taken into consideration when using this preparation. However, general synaptic connectivity between contralateral and dorsomedial motor regions of the slice appears to be preserved, and more importantly, the calcium activity in preBötC cultures reflects a consistent rhythmic pattern initiation in the ventral oscillatory group followed by fast bilateral synchronization and subsequent propagation of signal to dorsomedial regions. Pharmacological modulation of the rhythm using agonists for NK1 and µ-opioid receptors also mimics responses seen in acute slice (Gray et al. 1999), demonstrating that essential peptidergic modulating systems are intact in the cultures, at least at the Postsynaptic level.

Thus the preBötC slice culture preparation could be a useful model of respiratory rhythm generation that approximates the already widely used acute slice preparation and is amenable for optical and electrical stimulation and recording. The longevity of the culture preparation will facilitate molecular biological experiments and techniques, as well as any protocol that requires pharmacological perturbations lasting multiple days or weeks.
