**ABSTRACT:** Two methods used to measure dinitrogen ( $N_2$ ) fixation (acetylene reduction and  $^{15}N_2$  uptake) often result in different  $N_2$  fixation rates. Part of the discrepancy may arise from the observation that *Trichodesmium* can release a fraction of their recently fixed  $N_2$  as dissolved organic nitrogen (DON) and/or ammonium ( $NH_4^+$ ). To resolve outstanding issues regarding  $N_2$  fixation and the production of dissolved combined nitrogen (N) by *Trichodesmium*, we conducted a comprehensive analysis of  $N_2$  fixation and the production of DON and  $NH_4^+$  in cultures of *Trichodesmium* IMS101. We performed  $^{15}N_2$  uptake experiments in parallel with acetylene ( $C_2H_2$ ) reduction assays, and measured production of  $^{15}NH_4^+$  and  $DO^{15}N$  from  $^{15}N_2$ , and  $^{15}NH_4^+$  uptake and regeneration by isotope dilution. Four main results are highlighted. First,  $^{15}N_2$  uptake appears to provide a better approximation of net N-specific growth rates than  $N_2$  fixation estimates made using  $C_2H_2$  reduction. Second, the  $C_2H_2$  reduction method provides a closer approximation of gross  $N_2$  fixation. Third, simultaneous measurements of relevant N pools and pathways by several methods enabled us to rigorously evaluate deviations from theoretical conversion factors and to interpret the basis for those deviations. Our results suggest that a conversion ratio (mol  $C_2H_2$  reduced: mol  $N_2$  reduced to PON, ammonium and DON) of 4:1 may be more appropriate for total  $N_2$  fixation. Fourth, the difference between estimates of gross  $N_2$  fixation, made using the  $C_2H_2$  reduction technique, and net  $^{15}N_2$  uptake into particulate N may be a good indicator of N release from  $N_2$  fixation.

## INTRODUCTION

*Trichodesmium* spp. fix dinitrogen ( $N_2$ ), and thereby introduce new nitrogen (N) in regions where they occur. While this capability precludes N limitation of *Trichodesmium* growth and biomass accumulation, it is unclear how inputs of new N from  $N_2$  fixation affect nutrient cycling and productivity in the oligotrophic ocean in general. It has been reported that *Trichodesmium* spp. release upwards of 50% of recently

fixed  $N_2$  as dissolved organic N (DON) (Glibert & Bronk 1994); largely, it appears, as amino acids (Capone et al. 1994). In natural systems, this recently fixed N may provide combined N to support production by associated auto- and heterotrophs.

In culture systems, ammonium ( $NH_4^+$ ) appears to be the primary recycling intermediate for recently fixed  $N_2$  (Mulholland & Capone 2001). While  $N_2$  fixation accounted for the net production of new biomass, release and uptake of  $NH_4^+$  fueled additional and rapid

turnover of this pool. Previous research demonstrated that both dissolved free amino acids (DFAA) and  $\text{NH}_4^+$  accumulate in the culture medium during growth (Mulholland et al. 1999, Mulholland & Capone 2001), but only  $\text{NH}_4^+$  is simultaneously taken up under these conditions (see also Mulholland & Capone 1999). Subsequent results from kinetic experiments that examined  $\text{NH}_4^+$  uptake using incubation times of various lengths diverged widely; *Trichodesmium* showed a high affinity for  $\text{NH}_4^+$ , but the longer the incubation time, the lower the apparent maximum specific uptake rate ( $V_{\text{max}}$ ) (Mulholland et al. 1999; our Fig. 1). These results suggest that for  $\text{NH}_4^+$ , isotope dilution could be substantial (e.g. King & Berman 1984).

Though these earlier results indicated the potential importance of rapid  $\text{NH}_4^+$  release and uptake by *Trichodesmium*, not all relevant pools and processes were measured, e.g. direct release of DON and  $\text{NH}_4^+$ . The objective of this study was to obtain a more comprehensive picture of the fate of recently fixed  $\text{N}_2$ . To accomplish this, another series of culture experiments were conducted in which we directly measured  $\text{NH}_4^+$  uptake as well as the production of dissolved  $\text{NH}_4^+$  and DON from recently fixed  $\text{N}_2$  and  $\text{NH}_4^+$  regeneration by isotope dilution.

While culture systems do not mimic the complexity of population interactions observed in nature, we chose them as an effective tool to better understand and complement field estimates and to identify and isolate relevant pathways affecting the cycling of nutrients under defined physiological conditions. In nature, the prior physiological history and status of freshly collected *Trichodesmium* colonies or cells is generally unknown and biomass constraints often prevent the simultaneous measurement of relevant N cycling pathways.

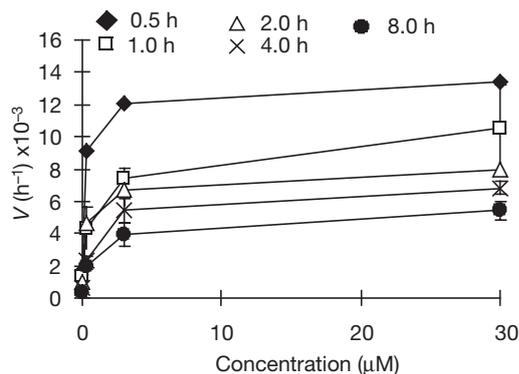

Fig. 1. Saturation kinetics for  $\text{NH}_4^+$  uptake in *Trichodesmium* NIBB1067 grown on medium without added N substrates during 0.5, 1.0, 2.0, 4.0 and 8.0 h incubations. Error bars represent the standard deviations from replicate uptake measurements.  $V$ : specific uptake rate

## MATERIALS AND METHODS

Rates of  $\text{N}_2$  fixation were measured by 2 methods: (1) using  $^{15}\text{N}$ -labeled  $\text{N}_2$ , which estimates net N accumulation into particulate organic nitrogen (PON); and (2) using the acetylene ( $\text{C}_2\text{H}_2$ ) reduction method, which estimates total  $\text{N}_2$  fixation. Likewise,  $\text{NH}_4^+$  regeneration was measured in 2 ways: (1) by adding  $^{15}\text{N}$ -labeled  $\text{N}_2$  gas and quantifying the appearance of  $^{15}\text{N}$  in the  $\text{NH}_4^+$  pool; and (2) by adding  $^{15}\text{N}$ -labeled  $\text{NH}_4^+$  and measuring the degree of isotope dilution over time (Glibert et al. 1982). DON was also isolated at the end of the  $^{15}\text{N}_2$  incubations so that rates of DON release could be measured directly. These measurements were made periodically over an entire growth cycle to quantify the effect of the population's changing physiological state.

Batch cultures of *Trichodesmium* IMS101 were grown on an artificial seawater medium without added N (Chen et al. 1996). While cultures were not entirely free of contaminating bacteria, their numbers were kept low by maintaining cultures in exponential phase growth and performing transfers using sterile techniques. Cultures were grown at 27°C on a 12:12 h light:dark cycle under cool, white fluorescent lighting, supplied at between 55 and 65  $\mu\text{mol quanta m}^{-2} \text{s}^{-1}$  PAR. Cells were routinely mixed to prevent their adhesion to the sides of the culture vessels.

Experiments were initiated by inoculating 34 replicate culture vessels containing N-free medium with equal volumes of an exponentially growing *Trichodesmium* parent culture. *Trichodesmium* filament counts, PON and chlorophyll *a* (chl *a*) biomass were used to establish growth rates of the culture during the 18 d experiment. At each sampling point (about every 2 d), samples were preserved with Lugol's solution and the number of filaments (or trichomes) enumerated microscopically. Concentrations of PON were measured on an ANCA GSL interfaced with a Europa GEO 20/20 isotope ratio mass spectrometer (IRMS) at the end of  $^{15}\text{N}$  experiments. Another set of samples were filtered onto pre-combusted (450°C for 2 h) GF/F filters and frozen for chl *a* analysis (spectrophotometric determination after extraction in methanol; Mackinney 1941); the filtrates were frozen for analysis of  $\text{NH}_4^+$  concentrations (autoanalyzer; Friederich & Whitledge 1972), DFAA (high performance liquid chromatography [HPLC]; Cowie & Hedges 1992) and total dissolved nitrogen (TDN) (persulfate oxidation; Bronk et al. 2000). DON was calculated as the difference between TDN and  $\text{NH}_4^+$ . Instrument error based on repeat injection was less than 10% for  $\text{NH}_4^+$  and DFAA analyses. Nitrate concentrations were always undetectable in previous culture experiments using media without added N, and so it was not measured during this study.

Prufert-Bebout et al. (1993) observed nitrate concentrations of about 0.5  $\mu\text{M}$  in cultures; however, these were grown on seawater-based media rather than the defined medium used for this study.

At each time point, samples for intracellular pools of  $\text{NH}_4^+$  and DFAA were also collected. For these measurements, an aliquot of culture was filtered through a 3.0  $\mu\text{m}$  filter and the retained *Trichodesmium* filaments and filters were rinsed with fresh medium. The filter tower was then placed onto an acid-cleaned filter flask and 25 ml of boiling deionized and distilled water was added to the filter tower (combined heat and osmotic shock; see Thoresen et al. 1982). The resulting filtrate was collected and frozen for analysis of dissolved  $\text{NH}_4^+$  and DFAA using the methods described above.

Over the course of the 18 d experiment, replicate cultures were sacrificed for rate measurements. All measurements were made simultaneously at mid-day because rates of  $\text{N}_2$  fixation are restricted to the light cycle and are maximal at or near mid-day. Rates of  $\text{N}_2$  fixation,  $\text{NH}_4^+$  uptake, and  $^{15}\text{NH}_4^+$  and  $\text{DO}^{15}\text{N}$  production from  $^{15}\text{N}_2$  were measured using highly enriched (96 to 99%)  $^{15}\text{N}_2$  and  $^{15}\text{NH}_4^+$  substrates as described below (Mulholland et al. 1999, Mulholland & Capone 2001). A previous study indicated that *Trichodesmium* might have significant intracellular pools of  $\text{NH}_4^+$  and DFAA (Mulholland et al. 1999). If this is the case, then  $\text{NH}_4^+$  and DON production from  $^{15}\text{N}_2$  might be underestimated. So, in addition, independent estimates of  $^{15}\text{NH}_4^+$  uptake and regeneration were made using the isotope dilution technique (Glibert et al. 1982). Because of culture volume constraints, isotope dilution experiments were not replicated.

Rates of  $\text{N}_2$  and  $\text{NH}_4^+$  uptake were measured using tracer additions (<10%) of highly enriched (99%)  $^{15}\text{N}_2$  and  $^{15}\text{NH}_4^+$  (Montoya et al. 1996, Mulholland & Capone 1999, 2001, Mulholland et al. 1999). For  $^{15}\text{N}_2$  uptake experiments, combusted (450°C overnight) Pyrex bottles (159 ml total volume) were filled to overflowing before being sealed with a septum cap (Teflon-lined butyl rubber). A gas-tight syringe was used to inject 160  $\mu\text{l}$  of  $^{15}\text{N}_2$  (Cambridge Isotopes Laboratories) into each incubation bottle as described by Montoya et al. (1996). Sample bottles were then replaced in the incubator. Ambient  $\text{N}_2$  concentrations in the culture bottles were calculated using the equations of Weiss (1970), assuming that cultures were at equilibrium with the atmosphere at the start of incubations. The resulting  $^{15}\text{N}_2$  additions were about 10%.  $^{15}\text{NH}_4^+$  uptake experiments were done in combusted 25 ml glass scintillation vials. Twenty ml of culture was placed in each vial and 0.03  $\mu\text{M}$   $^{15}\text{NH}_4^+$  (<10% of the ambient pool) was added to initiate incubations.

An advantage of measuring  $\text{N}_2$  fixation using  $^{15}\text{N}_2$  is that dissolved  $\text{NH}_4^+$  and DON pools can be isolated

and the production of dissolved  $^{15}\text{NH}_4^+$  and  $\text{DO}^{15}\text{N}$  can be measured in the sample filtrate from uptake experiments. The DON pool was isolated using ion retardation resin (Bronk & Glibert 1993, Bronk et al. 1998). The manufacturing process of the resin formally used in this isolation, BioRad AG 11 A8 (Bronk & Glibert 1991), changed in the early 1990s. As a result of the change, the resin now retains a variable amount of DON (Bronk 2002). The resin used in this study was manufactured in the Bronk lab by chemically altering another resin (Dowex anion exchange resin, BioRad AG1-X8) to produce AG 11 A8 using the method of Hatch et al. (1957). The resin produced in the lab did not retain DON, but had an isolation efficiency comparable to the original BioRad AG 11 A8 resin as described in Bronk & Glibert (1991). The  $\text{NH}_4^+$  pool was isolated with solid phase extraction (Dudek et al. 1986). The recovery from solid phase extraction was, on average, 35%. The low recovery is a result of the inefficiency in transferring the column eluate to a glass fiber filter prior to mass spectrometric analysis. Because the loss of sample does not result from a chemical reaction, there is no discernible isotopic fractionation. As in previous studies, rates of  $^{15}\text{NH}_4^+$  and  $\text{DO}^{15}\text{N}$  production from  $^{15}\text{N}_2$  were calculated using  $\text{N}_2$  as the source pool (Eq. 1; Glibert & Bronk 1994). This assumes that intracellular pools of  $\text{NH}_4^+$  and DON are minimal and that release of these compounds occurs prior to their assimilation into particulate N.

$$\frac{\text{NH}_4^+ \text{ or DON production}}{\text{atom\% excess NH}_4^+ \text{ or DON}} = \frac{\text{atom\% enrichment N}_2 \times \text{incubation time}}{\times [\text{NH}_4^+] \text{ or } [\text{DON}]} \quad (1)$$

Uptake of  $^{15}\text{N}_2$  and production of  $^{15}\text{NH}_4^+$  and  $\text{DO}^{15}\text{N}$  were measured in 2 h incubations that were initiated with the addition of  $^{15}\text{N}_2$  gas (99% enriched) and terminated by gentle filtration through pre-combusted (450°C for 2 h) GF/F filters.  $\text{NH}_4^+$  uptake and isotope dilution incubations were 1 h. Both were in the linear range of uptake during time courses conducted separately (data not shown). All  $^{15}\text{N}$  rate samples were analyzed on a Europa Geo 20/20 mass spectrophotometer as described above.

$\text{N}_2$  fixation rates were also estimated using the  $\text{C}_2\text{H}_2$  reduction technique (Capone 1993). Assays were initiated by adding 1 ml of  $\text{C}_2\text{H}_2$  to the headspace of serum vials containing 10 ml of culture. Immediately after the  $\text{C}_2\text{H}_2$  addition and at 30 min increments over 2 h, 500  $\mu\text{l}$  of headspace was removed and the production of ethylene was measured using a Shimadzu gas chromatograph. Ratios of 3:1 and 4:1 were used to convert rates of ethylene production ( $\text{C}_2\text{H}_2$  reduction) to  $\text{N}_2$  fixation (Montoya et al. 1996). Both of these ratios have been used in previous studies. While 3:1 is the theoret-

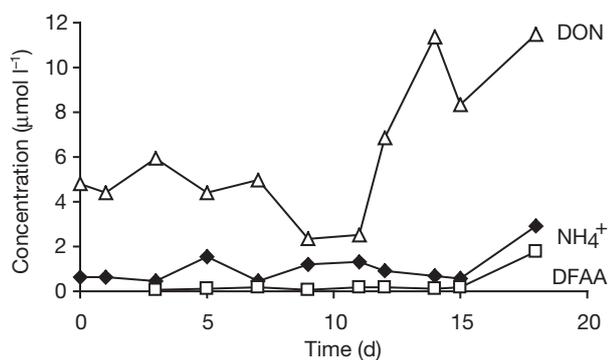

Fig. 4. Accumulation of  $\text{NH}_4^+$ , dissolved free amino acids (DFAA) and dissolved organic nitrogen (DON) in the culture medium of *Trichodesmium* IMS101 growing in batch culture on medium without added N sources, over the course of an 18 d growth cycle. Replicate samples were not collected. Standard deviations from replicate injections were <10% and so are not shown

mated using  $\text{C}_2\text{H}_2$  reduction versus  $^{15}\text{N}_2$  uptake methods might also be due to the release of recently fixed  $\text{N}_2$  as DON or  $\text{NH}_4^+$ . However, estimated rates of  $\text{NH}_4^+$  and DON production from  $^{15}\text{N}_2$  were also low compared with net  $^{15}\text{N}_2$  uptake and  $\text{C}_2\text{H}_2$  reduction throughout the growth cycle (Table 1) and relative to previous field estimates (Capone et al. 1994, Glibert & Bronk 1994). When rates of  $\text{NH}_4^+$  and DON production were added to net  $^{15}\text{N}_2$  uptake, to estimate total  $^{15}\text{N}_2$  uptake, this value was generally still much lower than estimates of  $\text{C}_2\text{H}_2$  reduction when assuming a 3:1 ratio throughout the experiment (Fig. 5). However, using a 4:1 ratio brings the  $\text{C}_2\text{H}_2$  reduction and  $^{15}\text{N}_2$ -based estimates much closer in line with total  $^{15}\text{N}_2$  fixation for Days 3 through 18 (Fig. 5, Table 1).

We derived an empirical conversion ratio for each time point by comparing the  $\text{C}_2\text{H}_2$  reduction rate directly to the net  $^{15}\text{N}_2$  uptake and total  $^{15}\text{N}_2$  uptake (the sum of net  $^{15}\text{N}_2$  uptake and  $^{15}\text{NH}_4^+$  and  $\text{DO}^{15}\text{N}$  production) (Table 1). In general, estimates were relatively close to the theoretical 3:1 ratio only on Day 1. In late exponential and early stationary phase, the 2 estimates likely diverge because of considerable release of  $\text{NH}_4^+$  and DON.

A summation of total N accumulated in the particulate and dissolved pools was also calculated for the cultures. There was an accumulation of  $162 \mu\text{mol l}^{-1}$  total N (PON, DON and  $\text{NH}_4^+$ ) over the 18 d experiment based on changes in these concentrations. Rates of net  $^{15}\text{N}_2$  uptake and  $^{15}\text{NH}_4^+$  and  $\text{DO}^{15}\text{N}$  production were

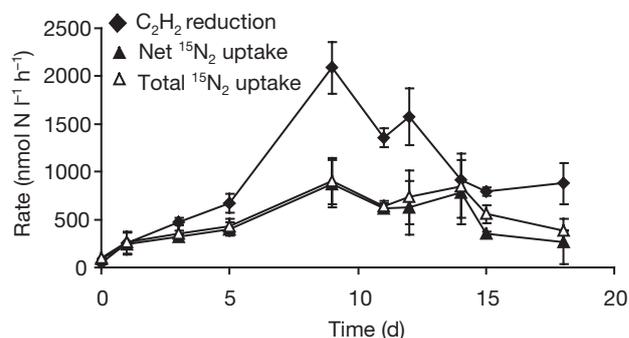

Fig. 5. Rates of  $\text{N}_2$  fixation estimated from net  $^{15}\text{N}_2$  uptake (uptake of  $^{15}\text{N}_2$  into PON collected on a GF/F filter at the end of the incubation); acetylene ( $\text{C}_2\text{H}_2$ ) reduction (conversion factor of 3:1); and total  $^{15}\text{N}_2$  uptake estimated by adding the rates of net  $^{15}\text{N}_2$  uptake,  $\text{DO}^{15}\text{N}$  production and  $^{15}\text{NH}_4^+$  production in batch cultures of *Trichodesmium* IMS101 growing on medium without added combined N. Error bars indicate standard deviations from replicate cultures

Table 1. Comparison of rates of  $\text{N}_2$  fixation estimated using acetylene ( $\text{C}_2\text{H}_2$ ) reduction, and conversion factors of 3 or 4, with rates of  $^{15}\text{N}_2$  uptake,  $^{15}\text{NH}_4^+$  and  $\text{DO}^{15}\text{N}$  production, and  $^{15}\text{NH}_4^+$  uptake with estimates of  $\text{NH}_4^+$  regeneration from isotope dilution corrected (IDC). Units are  $\text{nmol N l}^{-1} \text{h}^{-1}$ . The ratios of  $\text{N}_2$  fixation estimated by the acetylene reduction (AR) method and net or total  $^{15}\text{N}_2$  uptake are also compared. Standard deviation of replicate measurements in parentheses; na: no standard deviation was available

<sup>a</sup>mol  $\text{C}_2\text{H}_4$  formed: mol  $\text{N}_2$  fixed

integrated over the growth curve, interpolating between days on which no measurements were made and assuming these rates occurred over the 12 h light period (Fig. 6). Total  $^{15}\text{N}_2$  uptake (into particulate matter and recovered in the dissolved  $\text{NH}_4^+$  and DON pools) could account for  $125 \mu\text{mol l}^{-1} \text{N}$  of this accumulation. The rate measurements likely underestimate net N accumulation, but they were within the combined error of measurements made on replicate cultures, suggesting that  $^{15}\text{N}_2$  uptake and release of recently fixed  $\text{N}_2$  could account for N dynamics in cultures. Integrated  $\text{N}_2$  fixation, estimated using  $\text{C}_2\text{H}_2$  reduction with a 3:1 ratio, introduced  $225 \mu\text{mol N l}^{-1}$  new N to the culture system during this experiment, whereas assuming a 4:1 ratio yielded a value of  $169 \mu\text{mol N l}^{-1}$ , very close to that observed (Fig. 6).

Accumulation of PON estimated using total  $^{15}\text{N}_2$  uptake closely paralleled the observed growth rates in the cultures, while  $\text{C}_2\text{H}_2$  reduction-based estimates of PON accumulation were faster than the observed growth rates during most of the experiment (after Day 3).

#### $\text{NH}_4^+$ uptake, regeneration and isotope dilution

Despite the low estimates of  $\text{NH}_4^+$  production from  $^{15}\text{N}_2$ , rates of  $\text{NH}_4^+$  uptake were comparable to or higher than rates of  $^{15}\text{N}_2$  uptake during exponential growth (Table 1). When corrected for isotope dilution (see Glibert et al. 1982, Glibert & Capone 1993), uptake of  $\text{NH}_4^+$  exceeded rates of  $^{15}\text{N}_2$  uptake and were often comparable to rates of  $\text{N}_2$  fixation estimated by  $\text{C}_2\text{H}_2$  reduction (Table 1). Unlike estimates of  $^{15}\text{NH}_4^+$  release from  $^{15}\text{N}_2$  uptake, rates of  $\text{NH}_4^+$  regen-

eration estimated using the isotope dilution method were substantial and exceeded rates of  $^{15}\text{NH}_4^+$  production from recently fixed  $^{15}\text{N}_2$  by up to 2 orders of magnitude. Rates of  $\text{NH}_4^+$  uptake corrected for isotope dilution were comparable to rates of regeneration of  $\text{NH}_4^+$  from isotope dilution (Table 1), indicating rapid turnover and a tight coupling between  $\text{NH}_4^+$  uptake and release and consistent with the observation that  $\text{NH}_4^+$  did not accumulate in the culture medium (Fig. 4).

## DISCUSSION

### *Trichodesmium* uptake of $\text{NH}_4^+$ and DON

Early tracer studies suggested that *Trichodesmium* spp. had a relatively low capacity for uptake of combined N (Carpenter & McCarthy 1975, Glibert & Banahan 1988) and were primarily dependent upon  $\text{N}_2$  fixation to meet their N nutritional needs. Subsequent work, however, has found a relatively high capacity for  $\text{NH}_4^+$  assimilation in field populations and cultures (Mulholland & Capone 1999, 2000, Mulholland et al. 1999) although stable isotope (Carpenter et al. 1997) and culture studies (Mulholland & Capone 2001) still indicate that net growth is largely supported by  $\text{N}_2$  fixation. Adding to the complexity, high rates of DON release from recently fixed  $\text{N}_2$  have been observed in field studies (Capone et al. 1994, Glibert & Bronk 1994) and release of  $\text{NH}_4^+$  has been inferred, but not directly measured, in culture studies (Prufert-Bebout et al. 1993, Mulholland & Capone 2001). In order to obtain a broader understanding of N dynamics and metabolism by these organisms, we examined rates of  $\text{NH}_4^+$  and DON release from  $^{15}\text{N}_2$  uptake experiments, in parallel with estimates of  $\text{N}_2$  fixation using the  $\text{C}_2\text{H}_2$  reduction technique, and  $\text{NH}_4^+$  uptake and regeneration from isotope dilution in *Trichodesmium* cultures.

Like previous culture and field studies (Mulholland & Capone 1999, 2001, Mulholland et al. 1999), we observed rates of  $\text{NH}_4^+$  uptake that were comparable to or higher than rates of  $\text{N}_2$  fixation estimated by  $\text{C}_2\text{H}_2$  reduction. These high uptake rates are consistent with the stoichiometric imbalance between  $\text{CO}_2$  fixation and  $\text{N}_2$  fixation over a growth cycle (Mulholland & Capone 2001). Additional N turnover from  $\text{NH}_4^+$  regeneration and uptake within the culture vessels would not support net growth but could balance  $\text{CO}_2$  fixation in excess of that necessary to support the observed C accumulation as biomass. Alternatively, as we have previously speculated, the release and subsequent uptake of  $\text{NH}_4^+$  or other fixed N compounds may be a mechanism

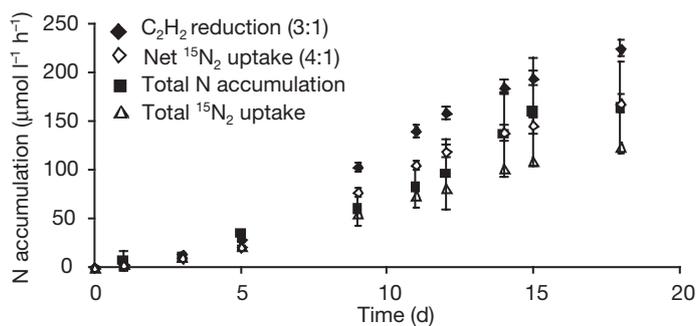

Fig. 6. Total accumulation of N in culture vessels over the course of the growth cycle estimated from acetylene reduction (using conversion factors of 3 and 4), total  $^{15}\text{N}_2$  uptake (estimated by adding the rates of net  $^{15}\text{N}_2$  uptake,  $\text{DO}^{15}\text{N}$  production and  $^{15}\text{NH}_4^+$  production), and the observed accumulation of total N (estimated by adding PON plus total dissolved N) in batch cultures of *Trichodesmium* IMS101 growing on medium without added combined N. Error bars indicate standard deviations from replicate cultures

whereby fixed N is transferred between cells capable of fixing  $N_2$  and those that are not (Mulholland & Capone 1999, 2000), as might be required by the cyanocyte model which argues that only a subset of the cells of a trichome are induced for  $N_2$  fixation (Berman-Frank et al. 2001).

Based on our results from  $^{15}N_2$  uptake experiments, the high rates of  $NH_4^+$  uptake observed in cultures of *Trichodesmium* cannot be supported by the measured release of recently fixed  $^{15}N_2$  as  $^{15}NH_4^+$ . In contrast, high rates of  $NH_4^+$  regeneration from isotope dilution suggest that in fact, release rates are substantial and that release and uptake are tightly coupled in these culture systems. The lack of  $NH_4^+$  accumulation in the growth medium over most of the growth cycle supports this, and the tight coupling precludes accurate estimates of gross  $NH_4^+$  release based on quantifying the accumulation of  $^{15}N$  label in the  $NH_4^+$  pool during  $^{15}N_2$  uptake studies.

### Release of $NH_4^+$ and DON

In contrast to 2 field studies (Capone et al. 1994, Glibert & Bronk 1994, O'Neil et al. 1996), observed rates of  $^{15}NH_4^+$  and  $DO^{15}N$  production from recently fixed  $^{15}N_2$  were low in the cultures. We discuss 2 potential reasons for these low rates: (1) the absence of grazers in the cultures; and (2) the presence of large intracellular pools of  $NH_4^+$  and DON in cultured *Trichodesmium*.

The presence of grazers and associated sloppy feeding is an important mechanism for the release of regenerated N (Bronk 2002). Rates of DON release were found to be significantly higher in the presence of

grazers in California coastal waters and DON release rates were closely correlated to  $NH_4^+$  regeneration (Ward & Bronk 2001). One grazer, the harpacticoid copepod *Macrosetella gracilis*, has been shown to feed on *Trichodesmium* colonies (O'Neil & Roman 1992, O'Neil 1998). These copepods do not appear to make solid fecal pellets such that most of the N they release remains in the dissolved fraction (O'Neil et al. 1996). Therefore, one likely reason for the lower rates of N release in this culture study was the absence of grazers.

Another contributing factor to the low rates of N release in the cultures may have been the presence of large intracellular pools of unlabeled  $NH_4^+$  and DON compounds (e.g. DFAA). Initial  $NH_4^+$  and DON release may have been isotopically light material that was present in cells prior to the  $^{15}N_2$  addition. Based on rates of total  $N_2$  uptake, it would have taken less than one to several hours to turn over the intracellular  $NH_4^+$  pool (Table 2) and, in most cases, even longer to turn over the intracellular DFAA pool. Hence, 2 h incubations may have been insufficient for the intermediate internal  $NH_4^+$  to reach isotopic equilibrium with the initial  $^{15}N_2$  tracer pool, thereby precluding accurate estimation of  $^{15}NH_4^+$  or  $DO^{15}N$  release rate. Similarly,  $NH_4^+$  regeneration based on isotope dilution can also be underestimated if the intracellular pools are emptied in less than the 1 h incubation period because  $^{15}NH_4^+$  taken up might be released. The total intracellular DON pools were not measured, but intracellular DFAA pools were often much larger than intracellular  $NH_4^+$  pools (e.g. Table 2) and so similar problems could have resulted in underestimates of  $DO^{15}N$  release from  $^{15}N_2$  uptake.

While these observations were made in cultured populations, we previously measured intracellular pools

Table 2. Comparison of trichome-specific  $N_2$  fixation rates, intracellular  $NH_4^+$  and PON pools and turnover of intracellular pools of  $NH_4^+$  (IN- $NH_4^+$ ) and PON based on  $N_2$  fixation estimates. Standard deviations of replicate measurements in parentheses

<sup>a</sup>Based on C<sub>2</sub>H<sub>2</sub> reduction

<sup>b</sup>Based on total  $^{15}N_2$  uptake

of DFAA and  $\text{NH}_4^+$  in natural populations of *Trichodesmium* (Mulholland et al. 1999). During those studies, intracellular pool concentrations were much lower (maximum of about 0.03 nmol  $\text{NH}_4^+$  filament<sup>-1</sup> and 0.06 nmol DFAA filament<sup>-1</sup>) than in this culture study, where the medium was nutrient replete (with respect to P and trace elements). However, biomass-specific  $\text{N}_2$  fixation rates are often lower and N-based turnover times longer in field studies (Mulholland & Capone 2000), and so these pools might still be sufficiently large to cause underestimates in N release from  $^{15}\text{N}_2$  uptake experiments for the reasons discussed above.

Simultaneous release and uptake of  $\text{NH}_4^+$  or DON on time-scales shorter than the incubation period would also bias both the measurements of  $^{15}\text{NH}_4^+$  or  $\text{DO}^{15}\text{N}$  production from  $^{15}\text{N}_2$  uptake and  $\text{NH}_4^+$  regeneration by the isotope dilution method because released material would not accumulate in the growth media. Correcting uptake calculations for isotope dilution yields much higher uptake rates than those derived without this correction (Table 1).  $\text{NH}_4^+$  uptake was often higher than total  $\text{N}_2$  fixation, particularly in the initial growth phases. Tightly coupled release and uptake of  $\text{NH}_4^+$  is supported by the observed  $\text{NH}_4^+$  concentrations, the high rates of  $\text{NH}_4^+$  regeneration from isotope dilution, and the absence of sustained  $\text{NH}_4^+$  accumulation over the growth cycle.

Tightly coupled release and uptake was likely the case for DON as well; however, no independent measure of DON regeneration was made. For DON, there is the additional problem of identifying the relevant production pool. For example, an earlier study suggested that the primary organic compounds released by *Trichodesmium* were DFAA (Capone et al. 1994).

### Comparing $^{15}\text{N}_2$ uptake with $\text{C}_2\text{H}_2$ reduction

One important component of the present study is the comprehensive analysis of  $^{15}\text{N}$  products from  $^{15}\text{N}_2$  uptake done in parallel with  $\text{C}_2\text{H}_2$  reduction determinations. As has been previously suggested (Carpenter 1973, Karl et al. 2002), we submit, and provide evidence to support, that  $\text{C}_2\text{H}_2$  reduction provides an estimate of gross  $\text{N}_2$  fixation, as it should assay all nitrogenase activity, whereas  $^{15}\text{N}_2$  uptake into particulate matter provides an estimate of net  $\text{N}_2$  fixation. Having simultaneous determination of  $^{15}\text{NH}_4^+$  and  $\text{DO}^{15}\text{N}$  production, we can rigorously evaluate deviations from theoretical conversion factors and interpret the basis for those deviations.

The relationship between  $^{15}\text{N}_2$  fixation and  $\text{C}_2\text{H}_2$  reduction is dependent upon a number of factors. For one, nitrogenase-dependent  $\text{H}_2$  release, which is inhibited by  $\text{C}_2\text{H}_2$ , results in a theoretical stoichiomet-

ric ratio of  $\text{C}_2\text{H}_2$  reduction to  $^{15}\text{N}_2$  fixation of 3:1 (mol:mol) (Postgate 1998). However, many cyanobacteria, including *Trichodesmium* (Saino & Hattori 1982, Scranton 1984, Scranton et al. 1987), have efficient uptake hydrogenases to recoup  $\text{H}_2$  lost during natural  $\text{N}_2$  fixation. This would drive the ratio closer to the theoretical 4:1 ratio.

Ratios of  $\text{C}_2\text{H}_2$  reduction to net  $^{15}\text{N}_2$  uptake greater than that theoretically predicted may also be indicative of substantial N release from  $\text{N}_2$  fixation. High rates of  $\text{NH}_4^+$  regeneration from isotope dilution in this study suggests that the release of recently fixed  $\text{N}_2$  is more substantial than production of  $^{15}\text{NH}_4^+$  from  $\text{N}_2$  would predict (for the reasons discussed above). Therefore, divergence of the  $\text{C}_2\text{H}_2$  reduction:net  $^{15}\text{N}_2$  uptake ratio from the theoretical ratio of 3:1 in the field studies may indicate that there was release of recently fixed  $\text{N}_2$ , especially where incubations were long. Extensive field studies (191 paired comparisons) suggest a mean ratio of  $\text{C}_2\text{H}_2$  reduction to net  $^{15}\text{N}_2$  uptake of about 3.6:1 (D. G. Capone et al. unpubl.). This is consistent with the observations that recently fixed  $\text{N}_2$  is released as DON (e.g. Capone et al. 1994, Glibert & Bronk 1994). In contrast, in an earlier culture study,  $\text{N}_2$  fixation estimated using  $\text{C}_2\text{H}_2$  reduction and a ratio of 3:1 more closely predicted the increase in PON (Mulholland & Capone 2001). Similarly, Orcutt et al. (2001) reported an average ratio of about 3:1, with considerable variance around that mean, for a multi-year study at the Bermuda Atlantic Time Series station.

### CONCLUSION

The current findings suggest that  $^{15}\text{N}_2$  uptake approximates net N-specific growth rates (Table 2, Fig. 6) while the  $\text{C}_2\text{H}_2$  reduction technique is a good estimator of gross  $\text{N}_2$  fixation. When considering total  $^{15}\text{N}_2$  fixation (sum of PON plus released DON and  $\text{NH}_4^+$ ), a conversion ratio of 4:1 is more appropriate for quantification of total  $\text{N}_2$  fixation when measured by  $\text{C}_2\text{H}_2$  reduction than that derived using the theoretical 3:1 conversion factor. Indeed, the difference between estimates of gross  $\text{N}_2$  fixation, made using the  $\text{C}_2\text{H}_2$  reduction technique and the theoretical 3:1 conversion factor, and net  $\text{N}_2$  fixation, made using  $^{15}\text{N}_2$ , is a good indicator of N release from  $\text{N}_2$  fixation.
