We have isolated charged-current quasielastic (QE) interactions occurring in the segmented scintillator tracking region of the MINERvA detector running in the NuMI neutrino beam at Fermilab. We measure the flux-averaged differential cross section, $d\sigma/dQ^2$, and compare to several theoretical models of QE scattering. Good agreement is obtained with a model where the nucleon axial mass, $M_A$, is...
The recent discovery that the neutrino mixing angle $\theta_{13} \approx 9^\circ$ [1–5] makes measuring the hierarchy of neutrino masses and CP violation possible in precision neutrino oscillation experiments. Quasielastic (QE) interactions, $\bar{\nu} p \to \ell^+ n$ and $\nu n \to \ell^- p$, have simple kinematics and serve as reference processes in those experiments [1,6,7] at GeV energies. These processes are typically modeled as scattering on free nucleons in a relativistic Fermi gas (RFG), with a nucleon axial form factor measured in neutrino-deuteron quasielastic scattering [8,9]. In the RFG model [10], the initial state nucleons are independent in the mean field of the nucleus, and therefore, the neutrino energy and momentum transfer $Q^2$ can be estimated from the polar angle $\theta$ and momentum $p_f$ of the final state lepton. However, correlations and motion of the initial state nucleons, as well as interactions of the final state particles within the nucleus, significantly modify the Fermi gas picture and affect the neutrino energy reconstruction in oscillation experiments [11–13].

Few measurements of antineutrino quasielastic scattering exist [14–16]. The most recent, from the MiniBooNE experiment on a hydrocarbon target at energies near 1 GeV [16], does not agree with expectations based on the RFG model described above. A MiniBooNE analysis of $\nu_\mu$ quasielastic scattering suggests an increased axial form factor at high $Q^2$ [17]. However, results at higher energy from the NOMAD experiment [18] are consistent with the Fermi gas model and the form factor from deuterium.

In this Letter, we report the first study of antineutrino quasielastic interactions from the MINERvA experiment, which uses a finely segmented scintillator detector at Fermilab to measure muon antineutrino and neutrino charged current interactions at energies between 1.5 and 10 GeV on nuclear targets. The signal reaction has a $\mu^-$ in the final state along with one or more nucleons (typically with a leading neutron), and no mesons [19]. The $\mu^-$ is identified by a minimum ionizing track that traverses MINERvA [20] and travels downstream to the MINOS magnetized spectrometer [21] where its momentum and charge are measured. The leading neutron, if it interacts, leaves only a fraction of its energy in the detector in the form of scattered low energy protons. To isolate quasielastic events from those where mesons are produced, we require the hadronic system recoiling against the muon to have a low energy. That energy is measured in two spatial regions. The vertex energy region corresponds to a sphere around the vertex with a radius sufficient to contain a proton (pion) with 120 (65) MeV kinetic energy. This region is sensitive to low energy protons which could arise from correlations among nucleons in the initial state or interactions of the outgoing hadrons in the target nucleus. We do not use the vertex energy in the event selection. The recoil energy region includes energy depositions outside of the vertex region and is sensitive to pions and higher energy nucleons. We use the recoil energy to estimate and remove inelastic backgrounds.

The MINERvA experiment studies neutrinos produced in the NuMI beam line [22] from 120 GeV protons which strike a graphite target. The mesons produced in $p + C$ interactions are focused by two magnetic horns into a 675 m long helium-filled decay pipe. The horns were set to focus negative mesons, resulting in a muon antineutrino enriched beam with a peak energy of 3 GeV. Muons produced in meson decays are absorbed in 240 m of rock downstream of the decay pipe. This analysis uses data taken between November 2010 and February 2011 with $1.014 \times 10^{20}$ protons on target.

A GEANT4-based [23,24] beam line simulation is used to predict the antineutrino flux. Hadron production in the simulation was tuned to agree with the NA49 measurements of pion production from 158 GeV protons on a thin carbon target [25]. FLUKA is used to translate NA49 measurements to proton energies between 12 and 120 GeV [26,27]. Interactions not constrained by the NA49 data are predicted using the FTFP hadron shower model [28].

The MINERvA detector consists of a core of scintillator strips surrounded by electromagnetic and hadronic calorimeters on the sides and downstream end of the detector [20,29]. The strips are perpendicular to the $z$ axis (which is very nearly the beam axis) and are arranged in planes with a 1.7 cm strip-to-strip pitch [30]. Three plane orientations ($0^\circ$, $\pm 60^\circ$ rotations around the $z$ axis) enable reconstruction of the neutrino interaction point, the tracks of outgoing charged particles, and calorimetric reconstruction of other particles in the interaction. The 3.0 ns timing resolution is adequate for separating multiple interactions within a single beam spill.

MINERvA is located 2 m upstream of the MINOS near detector, a magnetized iron spectrometer [21]. The MINERvA detector’s response is simulated by a tuned GEANT4-based [23,24] program. The energy scale of the detector is set by ensuring that both the photostatistics and the reconstructed energy deposited by momentum-analyzed through-going muons agree in data and simulation. Calorimetric constants used to reconstruct the energy of hadronic showers are determined from the simulation.

The uncertainty in the response to single hadrons is constrained by the measurements made with a scaled down version of the MINERvA detector in a low energy hadron test beam [20]. The MINERvA detector records the energy and time of energy depositions (hits) in each scintillator strip. Hits are first grouped in time and then clusters of energy are formed by spatially grouping the hits in each scintillator plane. Clusters with energy $>1$ MeV are then matched among the three views to create a track. The most upstream cluster on the muon track establishes the event vertex. We identify a $\mu^+$ by matching a track that exits the back of MINERvA with a positively charged track entering the front of MINOS. The per plane track resolution is $2.7 \text{ mm}$ and the angular resolution of the muon track is better than $10 \text{ mrad}$ [20]. 

The event vertex is restricted to be within the central 110 planes of the scintillator tracking region and no closer than $22 \text{ cm}$ to any edge of the planes. These requirements define a region with a mass of $5.57 \text{ metric tons}$.

The times of the tracked hits are used to determine the interaction time. Other untracked clusters up to $20 \text{ ns}$ before and $35 \text{ ns}$ after that time are associated with the event. The energy of the recoil system is calculated from the event vertex. We identify a $\mu^+$ by matching a track that exits the back of MINERvA with a positively charged track entering the front of MINOS by projecting tracks found in one of the detectors to the other and measuring the misreconstruction rate. This resulted in a $-7.8\%$ ($-4.6\%$) correction to the simulated efficiency for muons below (above) $3 \text{ GeV}/c$.

Event pileup causes a decrease in the muon track reconstruction efficiency. We studied this in both MINERvA and MINOS by projecting tracks found in one of the detectors to the other and measuring the misreconstruction rate. This resulted in a $-7.8\%$ ($-4.6\%$) correction to the simulated efficiency for muons below (above) $3 \text{ GeV}/c$.

Estimation of the initial neutrino energy ($E_{\nu}$) and four-momentum transfer squared ($Q^2$) of the interaction assumes an initial state nucleon at rest with a constant binding energy, $E_b$, which we set to $+30 \text{ MeV}$ based on electron scattering data [31,32] and estimates of Coulomb and asymmetry (Pauli) energy effects from the semiempirical mass formula for nuclei [33]. Under this quasielastic hypothesis, denoted by QE, 

$$E^{\text{QE}}_{\nu} = \frac{m_n^2 - (m_p - E_b)^2 - m_\mu^2 + 2(m_p - E_b)E_\mu}{2(m_p - E_b - E_\mu + p_\mu \cos \theta_\mu)},$$

(1)

$$Q^{2\text{QE}} = 2E^{\text{QE}}_\nu (E_\mu - p_\mu \cos \theta_\mu) - m_\mu^2,$$

(2)

where $E_\mu$ and $p_\mu$ are the muon energy and momentum, $\theta_\mu$ is the muon angle with respect to the beam, and $m_n$, $m_p$, and $m_\mu$ are the masses of the neutron, proton and muon, respectively.

Figure 1 shows the reconstructed data compared to neutrino interactions simulated using the GENIE 2.6.2 neutrino event generator [34]. For quasielastic interactions, the cross section is given by the Llewellyn Smith formalism [35]. Vector form factors come from fits to electron scattering data [36]; the axial form factor used is a dipole with an axial mass ($M_A$) of $0.99 \text{ GeV}/c^2$, consistent with deuteron measurements [8,9], and subleading form factors are assumed from partial conservation of the axial current (PCAC) or exact G-parity symmetry [37]. Inelastic reactions with a low invariant mass hadronic final state are based on a tuned model of discrete baryon resonance production [40], and the transition to deep inelastic scattering is simulated using the Bodek-Yang model [41].

![Figure 1](image1.png)

**FIG. 1** (color online). The measured recoil energy distribution (solid circles) and the predicted composition of signal and background. Backgrounds from charged-current (CC) baryon resonance production (light gray), continuum or deep-inelastic scattering (DIS) (dark gray), and other sources (black), such as coherent pion production, are shown. The fraction of signal in this sample, before requiring low recoil energy, is 0.58.

![Figure 2](image2.png)

**FIG. 2** (color online). The measured $Q^{2\text{QE}}$ distribution before background subtraction and corrections for detector resolutions and acceptance. The fraction of signal in this sample is 0.77, and 54% of signal events in our fiducial volume pass all selections.
state interactions, where hadrons interact within the target nucleus, are modeled using the INTRANUKE package [34].

Figure 1 shows evidence of quasielastic interactions in the peak of events at low recoil energy. A significant background of inelastic events still exists, primarily from baryon resonance production and decay where the final state pion is not identified. To reduce this background, we make a $Q_{OE}^2$ dependent selection of low recoil-energy events [42]. We also require $E_r^{QE} < 10$ GeV to limit uncertainties due to the neutrino flux. Figure 2 shows the $Q_{OE}^2$ distribution of the remaining 16,467 events in the data compared with the simulation.

The background in each $Q_{OE}^2$ bin is estimated from the data by fitting the relative normalizations of signal and background recoil energy distributions whose shapes are taken from the simulation. The fit results in a 10% reduction in the relative background estimate for $Q_{OE}^2 > 0.8$ GeV$^2$ and no change to $Q_{OE}^2 < 0.8$ GeV$^2$. We then correct for energy resolution using a Bayesian unfolding method [43] with four iterations to produce the event yield as a function of $Q_{OE}^2$, determined via Eq. (2) with $p_{\mu}$ and $\theta_{\mu}$ taken from the GENIE event generator. After unfolding, we use the simulation to correct the yield for efficiency and acceptance, and then divide by the neutrino flux and the number of target nucleons to calculate the bin-averaged cross section. We estimate the neutrino flux in the range $1.5 \leq E_\nu \leq 10.0$ GeV to be $2.43 \times 10^{-8}$ cm$^{-2}$ per proton on target [44], and there are $(1.91 \pm 0.03) \times 10^{30}$ protons in the fiducial volume.

The main sources of systematic uncertainty in the differential cross-section measurement are due to the reconstruction of the muon, the reconstruction and detector response for hadrons, the neutrino interaction model, final state interactions, and the neutrino flux. These uncertainties are evaluated by repeating the cross-section analysis with systematic shifts applied to the simulation, and their effect is shown in Table I.

Uncertainties in the muon energy scale have a direct impact on $Q_{OE}^2$ and result in a bin migration of events. The bulk of the uncertainty comes from MINOS, which reconstructs muon energy by range (for stopping tracks) and curvature (exiting). There is a 2.0% uncertainty in the range measurement, due to the material assay and imperfect knowledge of muon energy loss [21]. Using muon tracks which stop in the detector, we compare the momentum measured by range and curvature to establish an additional uncertainty of 0.6% (2.6%) on curvature measurements above (below) 1 GeV/c. We also account for subdominant uncertainties on the energy loss in MINERvA, systematic offsets in the beam angle, mismodeling of the angular and position resolution, and tracking efficiencies.

The systematic error on the recoil energy measurement is due to the uncertainty in the MINERvA detector energy scale set by muons and differences between the simulated calorimetric response to single hadrons and the response measured by the test beam program. Additional uncertainties are evaluated by repeating the cross-section analysis with systematic shifts applied to the simulation, and their effect is shown in Table I.

uncertainties are due to differences between the GEANT model of neutron interactions and thin target data on neutron scattering in carbon, iron, and copper [45–52]. We evaluate further sources of systematic error by loosening analysis cuts on energy near the vertex and on extra isolated energy depositions, repeating the fit to the background and subsequent analysis, and assigning an uncertainty to cover the difference.

Predictions for $Q_{\text{QE}}^2$ and recoil energy distributions for neutrino-induced background processes are based upon the GENIE generator. We evaluate the systematic error by varying the underlying model tuning parameters according to their uncertainties [34]. These include parameters governing inelastic interactions of neutrinos with nucleons and those that vary the final state interactions.

The systematic error on the antineutrino flux arises from uncertainties in hadron production in the NuMI target and beam line, and from imperfect modeling of the beam line focusing and geometry [53]. Where hadron production is constrained by NA49 data [25], the NA49 measurement uncertainties dominate. The uncertainty on other interactions is evaluated from the spread between different GEANT4 hadron production models [23,24]. The absolute flux uncertainties are large, with a significant $E_{\nu}$ dependence, but mostly cancel in a measurement of the shape of $d\sigma/dQ_{\text{QE}}^2$.

The measured differential cross section $d\sigma/dQ_{\text{QE}}^2$ is shown in Fig. 3 and Table II. Averaged over the flux from 1.5 to 10 GeV, we find $\sigma = 0.604 \pm 0.008(\text{stat}) \pm 0.075(\text{syst}) \times 10^{-38} \text{cm}^2/\text{proton}$. As noted above, the systematic uncertainties are significantly reduced in the shape of the differential cross section [44], which is shown in Fig. 4.

Table III compares the data to the RFG model in the GENIE event generator and a number of different nuclear models and values of $M_A$ in the NuWro generator [54]. There is little sensitivity to replacement of the Fermi gas with a SF model of the target nucleon energy-momentum relationship [55]. The data disfavor $M_A = 1.35 \text{ GeV}/c^2$ as extracted from fits of the MiniBooNE neutrino quasielastic data in the RFG model [17]. Our data are consistent with a transverse enhancement model (TEM) which has $M_A = 0.99 \text{ GeV}/c^2$ in agreement with deuterium data and includes an enhancement of the magnetic form factors of bound nucleons that has been observed in electron-carbon scattering [56]. The $M_A = 1.35 \text{ GeV}/c^2$ and TEM models have a similar $Q_{\text{QE}}^2$ dependence at low $Q_{\text{QE}}^2$ but are distinguished by the kinematic reach of the data at $Q_{\text{QE}}^2 > 1 \text{ GeV}^2$.

Transverse enhancement is included as a parametrization affecting the $Q_{\text{QE}}^2$ dependence in our analysis but is thought to be due to underlying multinucleon dynamical processes [57–63]. Such processes could have an effect on the vertex and recoil energy distributions that we do not simulate. Motivated by these concerns and by discrepancies observed in our analysis of $\nu_\mu$ quasielastic scattering [64], we have also studied the vertex energy to test the simulation of the number of low energy charged particles emitted in quasielastic interactions. Figure 5 shows this energy compared to the simulation. A fit which modifies the distributions to incorporate energy due to additional protons is not able to achieve better agreement. This might be explained if the dominant multibody process is

![FIG. 5. Reconstructed vertex energy of events passing the selection criteria compared to the GENIE RFG model for $Q_{\text{QE}}^2 < 0.2 \text{ GeV}^2/c^2$ (left) and for $Q_{\text{QE}}^2 > 0.2 \text{ GeV}^2/c^2$ (right).](image)

### TABLE III. Comparisons between the measured $d\sigma/dQ_{\text{QE}}^2$ (or its shape in $Q_{\text{QE}}^2$) and different models implemented using the NuWro neutrino event generator, expressed as $\chi^2$ per degree of freedom (DOF) for eight (seven) degrees of freedom. The $\chi^2$ computation in the table accounts for significant correlations between the data points caused by systematic uncertainties.

\( \bar{\nu}_\mu (np) \rightarrow \mu^+ nn \) [57,60,65] since MINERvA is not very sensitive to low energy neutrons. A similar analysis on neutrino mode data is consistent with additional protons in the final state [64].

This work was supported by the Fermi National Accelerator Laboratory under United States Department of Energy (DOE) Office of High Energy Physics Contract No. DE-AC02-07CH11359 which included the MINERvA construction project. Construction support also was granted by the United States National Science Foundation (NSF) under Grant No. PHY-0619727 and by the University of Rochester. Support for participating scientists was provided by NSF and DOE (U.S.A.) by CAPES and CNPq (Brazil), by CONICYT (Chile), by CONCYTEC, DGI-PUCP, and IDI/IGI-UNI (Peru), by Latin American Center for Physics CONICYT (Chile), by CONCYTEC, DGI-PUCP, and IDI/IGI-UNI (Peru), by Latin American Center for Physics (CLAF), and by RAS and the Russian Ministry of Education and Science (Russia). We thank the MINOS Collaboration for use of its near detector data. Finally, we thank the staff of Fermilab for support of the beam line and the detector.
