Project Summary

As the spatial and temporal dynamics of marine ecosystems have recently become better understood, the concept of entirely closing or limiting activities in certain areas has gained support as a method to conserve and enhance marine resources. In the last decade, the sea scallop resource has benefited from measures that have closed specific areas to fishing effort. As a result of closures on both Georges Bank and in the mid-Atlantic region, biomass of scallops in those areas has expanded. As the time approaches for the fishery to harvest scallops from the closed areas, quality, timely and detailed stock assessment information is required for managers to make informed decisions about the re-opening.

During June 2013, a survey was conducted in the access area of the Nantucket Lightship Closed Area (NLCA) aboard a commercial sea scallop vessel. At pre-determined sampling stations within the NLCA, both a NMFS sea scallop survey dredge and a Coonamessett Farm Turtle Deflector Dredge (CFTDD) were simultaneously towed. From the catch data obtained on this cruise, fine scale survey information was used to assess scallop abundance and distribution in the access area. These data will also provide a comparison of the utility of using two different gears as survey tools in the context of industry based surveys.

Results indicate that the resource in NLCA is relatively abundant with sufficient exploitable biomass to support a commercial opening in 2014 and potentially in 2015. Of great interest was the observation of a significant recruiting class of scallops. These animals were present in very high densities in the southern portion of the area where settlement is rarely observed. This year class, which has the potential to extend well to the east and west, can potentially represent a major recruitment event for Georges Bank. Gear performance of the CFTDD was observed to be consistent with prior results with respect to the size of animals captured, although the relative efficiency of the CFTDD was slightly lower with respect to prior surveys.
Project Background

The sea scallop, *Placopecten magellanicus*, supports a fishery that in the 2012 fishing year landed 56.8 million pounds of meats with an ex-vessel value of over US $558 million (Lowther, 2013). These landings resulted in the sea scallop fishery being the most valuable single species fishery along the East Coast of the United States. While historically subject to extreme cycles of productivity, the fishery has benefited from management measures intended to bring stability and sustainability. These measures include: limiting the number of participants, total effort (days-at-sea), gear and crew restrictions and most recently, a strategy to improve yield by protecting scallops through rotational area closures.

Amendment #10 to the Sea Scallop Fishery Management Plan officially introduced the concept of area rotation to the fishery. This strategy seeks to increase the yield and reproductive potential of the sea scallop resource by identifying and protecting discrete areas of high densities of juvenile scallops from fishing mortality. By delaying capture, the rapid growth rate of scallops is exploited to realize substantial gains in yield over short time periods. In addition to the formal attempts found in Amendment #10 to manage discrete areas of scallops for improved yield, specific areas on Georges Bank are also subject to area closures. In 1994, 17,000 km² of bottom were closed to any fishing gears capable of capturing groundfish. This closure was an attempt to aid in the rebuilding of severely depleted species in the groundfish complex. Since scallop dredges are capable of capturing groundfish, scallopers were also excluded from these areas. Since 1999, however, limited access to the three closed areas on Georges Bank has been allowed to harvest the dense beds of scallops that have accumulated in the absence of fishing pressure.

In order to effectively regulate the fishery and carry out a robust rotational area management strategy, current and detailed information regarding the abundance and distribution of sea scallops is essential. Currently, abundance and distribution information gathered by surveys comes from a variety of sources. The annual NMFS sea scallop survey provides a comprehensive and synoptic view of the resource from Georges Bank to Virginia. In contrast to the NMFS survey that utilizes a dredge as the sampling gear, the resource is also surveyed optically. Researchers from the School for Marine Science and Technology (SMAST) and the Woods Hole Oceanographic Institute (WHOI) are able to enumerate sea scallop abundance and distribution from images taken by both a still camera and a towed camera system (Stokesbury, *et. al.*, 2004; Stokesbury, 2002). Prior to the utilization of the optical surveys and in addition to the annual information supplied by the NMFS annual survey, commercial vessels were contracted to perform surveys. Dredge surveys of the scallop access areas have been
successfully completed by the cooperative involvement of industry, academic and governmental partners. The additional information provided by these surveys was vital in the determination of appropriate Total Allowable Catches (TAC) in the subsequent re-openings of the closed areas. This type of survey, using commercial fishing vessels, provides an excellent opportunity to gather required information and also involve stakeholders in the management of the resource.

The passing of Amendment #10 has set into motion changes to the sea scallop fishery that were designed to ultimately improve yield and create stability. This stability is an expected result of a spatially explicit rotational area management strategy where areas of juvenile scallops are identified and protected from harvest until they reach an optimum size. Implicit to the institution of the new strategy, is the highlighted need for further information to both assess the efficacy of an area management strategy and provide that management program with current and comprehensive information. In addition to rotational management areas, access to the scallop biomass encompassed by the Nantucket Lightship Closed Area is vital to the continued prosperity of the fishery.

In addition to collecting data to assess the abundance and distribution of sea scallops in the NLCA, the operational characteristics of commercial scallop vessels allow for the simultaneous towing of two dredges. As in past surveys, we towed two dredges at each survey station. One dredge was a standard NMFS sea scallop survey dredge and the other was a Coonamessett Farm Turtle Deflector Dredge (CFTDD). This paired design, using one non-selective gear (NMFS) and one selective gear (CFTDD), allowed for the estimation of the size selective characteristics of the CFTDD equipped with turtle excluder chains. Gear performance (i.e. size selectivity and relative efficiency) information is limited for this dredge design and understanding how this dredge impacts the scallop resource will be beneficial for two reasons. First, it will be an important consideration for the stock assessment for scallops in that it provides the size selectivity characteristics of the most recent gear configuration and second, this information will support the use of this gear configuration to sample closed areas prior to re-openings. In addition, selectivity analyses using the SELECT method provide insight to the relative efficiency of the two gears used in the study (Millar, 1992). The relative efficiency measure from this experiment can be used to refine existing absolute efficiency estimates for the New Bedford style scallop dredge.

An advantage of a sea scallop dredge survey is that one can access and sample the target species. This has a number of advantages including accurate measurement of animal length and the ability to collect biological specimens. One attribute routinely measured is the shell height:meat weight relationship. While this relationship is used to determine swept area
biomass for the area surveyed at that time, it can also be used to document seasonal shifts in the relationship due to environmental and biological factors. For this reason, data on the shell height:meat weight relationship is routinely gathered by both the NMFS and VIMS scallop surveys. While this relationship may not be a direct indicator of animal health in and of itself, long term data sets may be useful in evaluating changing environmental conditions, food availability and density dependent interactions.

For this study, we pursued multiple objectives. The primary objective was to collect information to characterize the abundance and distribution of sea scallops within the access area of NLCA, ultimately culminating in an estimate of scallop biomass to be used in a subsequent management action. Utilizing the same catch data with a different analytical approach, we estimated the size selectivity characteristics of the commercial sea scallop dredge. An additional component of the selectivity analysis allows for supplementary information regarding the efficiency of the commercial dredge relative to the NMFS survey dredge. As a third objective of this study, we collected biological samples to estimate a time and area specific shell height:meat weight relationship. Additional biological samples were taken to assess product quality for the adult resource in the NLCA.

**Methods**

*Survey Area and Sampling Design*

The access area NLCA was surveyed during the course of this project. The boundary coordinates of the surveyed areas can be found in Table 1. Sampling stations for this study were selected within the context of a systematic random grid. With the patchy distribution of sea scallops determined by some unknown combination of environmental gradients (i.e. latitude, depth, hydrographic features, etc.), a systematic selection of survey stations results in an even dispersion of samples across the entire sampling domain. This sampling design has been successfully implemented during industry-based surveys since 1998.

The methodology to generate the systematic random grid entailed the decomposition of the domain (in this case a closed area) into smaller sampling cells. The dimensions of the sampling cells were primarily determined by a sample size analysis conducted using the catch data from survey trips conducted in the same areas during prior years. Since closed areas are of different dimensions and the total number of stations sampled per survey remains fairly constant, the distance between the stations varies. Generally, the distance between stations is roughly 3-4 nautical miles. Once the cell dimensions were set, a point within the most northwestern cell was randomly selected. This point served as the starting point and all of the other stations in the grid
were based on its coordinates. The station locations for the 2013 NLCA survey are shown in Figure 1.

**Sampling Protocols**

While at sea, the vessels simultaneously towed two dredges. A NMFS sea scallop survey dredge, 8 feet in width equipped with 2-inch rings, 3.5-inch diamond mesh twine top and a 1.5-inch diamond mesh liner was towed on one side of the vessel. On the other side of the vessel, a 15 foot Coonamessett Farm Turtle Deflector Dredge (CFTDD) equipped with 4-inch rings, a 10-inch diamond mesh twine top and no liner was utilized. Turtle chains were used in configurations as dictated by the area surveyed and current regulations. In this paired design, it is assumed that the dredges cover a similar area of substrate and sample from the same population of scallops.

For each survey tow, the dredges were fished for 15 minutes with a towing speed of approximately 3.8-4.0 kts. High-resolution navigational logging equipment was used to accurately determine and record vessel position. A Star-Oddi™ DST sensor was used on the dredge to measure and record dredge tilt angle as well as depth and temperature (Figure 2). With these measurements, the start and end of each tow was estimated. Synchronous time stamps on both the navigational log and DST sensor were used to estimate the linear distance for each tow. A histogram depicting the estimated linear distances covered per tow over the entire survey is shown in Figure 3.

Sampling of the catch was performed using the protocols established by DuPaul and Kirkley, 1995 and DuPaul et al. 1989. For each survey tow, the entire scallop catch was placed in baskets. Depending on the total volume of the catch, a fraction of these baskets were measured for sea scallop length frequency. The shell height of each scallop in the sampled fraction was measured on Lat 37 Fish Measuring Boards in 1 mm intervals. This protocol allows for the estimation of the size frequency for the entire catch by multiplying the catch at each shell height by the fraction of total number of baskets sampled. Finfish and invertebrate bycatch were quantified, with commercially important finfish being sorted by species and measured to the nearest 1 mm.

Samples were taken to determine area specific shell height:meat weight relationships. At roughly 25 randomly selected stations the shell height of 10 randomly selected scallops were measured to the nearest 0.1 mm. These scallops were then carefully shucked and the adductor muscle individually packaged and frozen at sea. Upon return, the adductor muscle was weighed to the nearest 0.01 gram. The relationship between shell height and meat weight was
estimated using a generalized linear mixed effects model (gamma distribution, log link, random
effect at the station level) incorporating depth as an explanatory variable using PROC GLIMMIX
in SAS v. 9.3. The relationship was estimated with the following models:

\[
MW = \exp(\alpha + \beta \ln(SH))
\]
\[
MW = \exp(\alpha + \beta \ln(SH) + \gamma \ln(\text{Depth}))
\]

where \(MW=\)meat weight (grams), \(SH=\)shell height (millimeters), \(\text{Depth}=\)depth (meters). \(\alpha, \beta\)
and \(\gamma\) are parameters to be estimated.

The standard bridge log data sheets in service since the 1998 Georges Bank survey were
used. Data recorded on the bridge log included GPS location, tow-time (break-set/haul-back),
tow speed, water depth, catch, bearing, weather and comments relative to the quality of the tow.
The deck log, maintained by the scientific personnel, recorded detailed catch information on
scallops, finfish, invertebrates and trash.

Data Analysis

The catch and navigation data were used to estimate swept area biomass within the area
surveyed. The methodology to estimate biomass is similar to that used in previous survey work
by VIMS. In essence, we estimate a mean catch weight of either all scallops or the fraction
available to the commercial gear (exploitable) from the point estimates and scale that value up
to the entire area of the domain sampled. This calculation is given:

\[
\text{TotalBiomass} = \sum_j \left( \frac{\text{CatchWiperTowinSubarea}_j}{\text{AreaSweptperTow}_j \cdot \text{Efficiency}} \right) \cdot \text{SubArea}_j
\]

Catch weight per tow of exploitable scallops was calculated from the raw catch data as an
expanded size frequency distribution with an area and depth appropriate shell height:meat
weight relationship applied (length-weight relationships were obtained from the SARC 50
document as well as the actual relationship taken during the cruise) (NEFSC, 2010).
Exploitable biomass, defined as that fraction of the population vulnerable to capture by the
currently regulated commercial gear, was calculated using two approaches. The observed
catch at length data from the NMFS survey dredge (assumed to be non-size selective) was adjusted based upon the size selectivity characteristics of the commercial gear (Yochum and DuPaul, 2008). The observed catch-at-length data from the commercial dredge was not adjusted due to the fact that these data already represent that fraction of the population that is subject to exploitation by the currently regulated commercial gear.

Utilizing the information obtained from the high resolution GPS, an estimate of area swept per tow was calculated. Throughout the cruise, the location of the ship was logged every two seconds. By determining the start and end of each tow based on the recorded times as delineated by the tilt sensor data, a survey tow can be represented by a series of consecutive coordinates (latitude, longitude). The linear distance of the tow is calculated by:

\[
TowDist = \sum_{i=1}^{n} \sqrt{(\text{long}_2 - \text{long}_1)^2 + (\text{lat}_2 - \text{lat}_1)^2}
\]

The linear distance of the tow is multiplied by the width of the gear (either 15 or 8 ft.) to result in an estimate of the area swept during a given survey tow.

The final two components of the estimation of biomass are constants and not determined from experimental data obtained on these cruises. Estimates of survey dredge gear efficiency have been calculated from a prior experiment using a comparison of optical and dredge catches (NEFSC, 2010). Based on this experiment, an efficiency value for the NMFS survey dredge of 38% was estimated for the rocky substrate areas on Georges Bank and a value of 44% was estimated for the smoother (sand, silt) substrates of some portions of Georges Bank and the entire mid-Atlantic. Estimates of commercial sea scallop dredge gear efficiency have been calculated from prior experiments using a variety of approaches (Gedamke et al., 2005, Gedamke et al., 2004, D. Hart, pers. comm.). The efficiency of the commercial dredge is generally considered to be higher and based on the prior work as well as the relative efficiency from the data generated from this study; an efficiency value of 60% was used for the NLCA. To scale the estimated mean scallop catch to the full domain, the total area of the NLCA was calculated in ArcGIS v. 10.0.

**Size Selectivity**

The estimation of size selectivity of the CFTDD equipped with 4” rings, a 10” twine top and turtle chains was based on a comparative analysis of the catches from the two dredges used in the survey. For this analysis, the NMFS survey dredge is assumed to be non-selective.
(i.e. a scallop that enters the dredge is retained by the dredge). Catch at length from the
selective gear (commercial dredge) were compared to the non-selective gear via the SELECT
method (Millar, 1992). With this analytical approach, the selective properties (i.e. the length
based probability of retention) of the commercial dredge were estimated. In addition to
estimates of the length based probabilities of capture by the commercial dredge, the SELECT
method characterizes a measure of relative fishing intensity. Assuming a known quantity of
efficiency for one of the two gears (in this case the survey dredge at 38%), insight into the
efficiency of the other gear (commercial dredge) can be attained.

Prior to analysis, all comparative tows were evaluated. Any tows that were deemed to
have had problems during deployment or at any point during the tow (flipped, hangs, crossed
towing wires, etc.) were removed from the analysis. In addition, tows where zero scallops were
captured by both dredges were also removed from the analysis. The remaining tow pairs were
then used to analyze the size selective properties of the commercial dredge with the SELECT
method.

The SELECT method has become the preferred method to analyze size-selectivity
studies encompassing a wide array of fishing gears and experimental designs (Millar and Fryer,
1999). This analytical approach conditions the catch of the selective gear at length \( l \) to the total
catch (from both the selective gear variant and small mesh control).

\[
\Phi_r(l) = \frac{p_r(l)}{p_r(l) + (1 - p_c)}
\]

Where \( r(l) \) is the probability of a fish at length \( l \) being retained by the gear given contact and \( p \)
is the split parameter (measure of relative efficiency). Traditionally, selectivity curves have been
described by the logistic function. This functional form has symmetric tails. In certain cases,
other functional forms have been utilized to describe size selectivity of fishing gears. Examples
of different functional forms include Richards, log-log and complimentary log-log. Model
selection is determined by an examination of model deviance (the likelihood ratio statistic for
model goodness of fit) as well as Akaike Information Criterion (AIC) (Xu and Millar, 1993, Sala,
et. al., 2008). For towed gears, however, the logistic function is the most common functional
form observed in towed fishing gears. Given the logistic function:

\[
r(l) = \frac{\exp(a + bl)}{1 + \exp(a + bl)}
\]
by substitution:

$$
\Phi(L) = \frac{pr(L)}{(1 - p) + pr(L)} = \frac{pe^{a+bl}}{1 + e^{a+bl}} = \frac{pe^{a+bl}}{(1 - p) + e^{a+bl}}
$$

Where $a$, $b$, and $p$ are parameters estimated via maximum likelihood. Based on the parameter estimates, $L_{50}$ and the selection range (SR) are calculated.

$$
L_{50} = \frac{-a}{b} \quad \text{SR} = \frac{2*\ln(3)}{b}
$$

Where $L_{50}$ defines the length at which an animal has a 50% probability of being retained, given contact with the gear and SR represents the difference between $L_{75}$ and $L_{25}$ which is a measure of the slope of the ascending portion of the logistic curve.

In situations where catch at length data from multiple comparative tows is pooled to estimate an average selectivity curve for the experiment, tow by tow variation is often ignored. Millar et al. (2004) developed an analytical technique to address this between-haul variation and incorporate that error into the standard error of the parameter estimates. Due to the inherently variable environment that characterizes the operation of fishing gears, replicate tows typically show high levels of between-haul variation. This variation manifests itself with respect to estimated selectivity curves for a given gear configuration (Fryer 1991, Millar et. al., 2004). If not accounted for, this between-haul variation may result in an underestimate of the uncertainty surrounding estimated parameters increasing the probability of spurious statistical significance (Millar et. al., 2004).

Approaches developed by Fryer (1991) and Millar et. al., (2004) address the issue of between-haul variability. One approach formally models the between-haul variability using a hierarchical mixed effects model (Fryer 1991). This approach quantifies the variability in the selectivity parameters for each haul estimated individually and may be more appropriate for complex experimental designs or experiments involving more than one gear. For more straightforward experimental designs, or studies that involve a single gear, a more intuitive combined-haul approach may be more appropriate.
This combined-hauls approach characterizes and then calculates an overdispersion correction for the selectivity curve estimated from the catch data summed over all tows, which is identical to a curve calculated simultaneously to all individual tows. Given this identity, a replication estimate of between-haul variation (REP) can be calculated and used to evaluate how well the expected catch using the selectivity curve calculated from the combined hauls fits the observed catches for each individual haul (Millar et. al. 2004).

REP is calculated as the Pearson chi-square statistic for model goodness of fit divided by the degrees of freedom.

\[ REP = \frac{Q}{d} \]

Where Q is equal to the Pearson chi-square statistic for model goodness of fit and d is equal to the degrees of freedom. The degrees of freedom are calculated as the number of terms in the summation, minus the number of estimated parameters. The calculated replicate estimate of between-haul variation was used to calculate observed levels of extra Poisson variation by multiplying the estimated standard errors by \( \sqrt{REP} \). This correction is only performed when the data is not overdispersed (Millar, 1993).

A significant contribution of the SELECT model is the estimation of the split parameter which estimates the probability of an animal “choosing” one gear over another (Holst and Revill, 2009). This measure of relative efficiency, while not directly describing the size selectivity properties of the gear, is insightful relative to both the experimental design of the study as well as the characteristics of the gears used. A measure of relative efficiency (on the observational scale) can be calculated in instances where the sampling intensity is unequal. In this case, the sampling intensity is unequal due to differences in dredge width. Relative efficiency can be computed for each individual trip by the following formula:

\[ RE = \frac{p / (1 - p)}{p_0 / (1 - p_0)} \]

Where \( p \) is equal to the observed (estimated \( p \) value) and \( p_0 \) represents the expected value of the split parameter based upon the dredge widths in the study (Park et. al., 2007). For this study, a 15 ft. commercial dredge was used with expected split parameter of 0.6521. The computed relative efficiency values were then used to scale the estimate of the NMFS survey.
dredge efficiency obtained from the optical comparisons (38%). Computing efficiency for the estimated p value from Yochum and DuPaul (2008) yields a commercial dredge efficiency of 67.8%. Preliminary observations suggest a slightly higher efficiency of the CFTDD relative to the standard New Bedford style scallop dredge that was used in Yochum and DuPaul (2008). This selectivity analysis will provide an additional piece of evidence related to the efficiency of the CFTDD.

**Results**

*Abundance and distribution*

The survey cruise to the access area of the NLCA was completed in June 2013. Summary statistics for the cruise are shown in Table 2. Length frequency distributions for the scallops captured during the NLCA survey are shown in Figure 4. Maps depicting the spatial distribution of the catches of pre-recruit (<90 mm shell height), and fully recruited (≥90 mm shell height) scallops from both the commercial and survey dredges are shown in Figures 5-8. Mean total and mean exploitable scallop densities for both the survey and commercial dredge are shown in Table 3. This information expanded to the area of the entire NLCA and representing an estimate of the total number of animals in the area is shown in Table 4. The mean estimated scallop meat weight for both the commercial and survey dredges for all of the shell height:meat weight relationships used is shown in Table 5. Mean catch (in grams of scallop meat) for the two dredge configurations as well as the two shell height: meat weight relationships are shown in Table 6. Total and exploitable biomass for both shell height:meat weight relationships and levels of assumed gear efficiency are shown in Tables 7-8 (total biomass from the CFTDD catch data is not estimated due to the selective properties of the commercial gear). Shell height:meat weight relationships were generated for the area. The resulting parameters as well as the parameters from SARC 50 (both a NLCA specific as well as a general Georges Bank relationship) are shown in Table 9. A comparative plot of the three curves is shown in Figure 9. Catch per unit of effort for finfish and invertebrate bycatch is shown in Table 10.

*Size selectivity*

The catch data were evaluated by the SELECT method with a variety of functional forms (logistic, Richards, log-log) in an attempt to characterize the most appropriate model. Examination of residual patterns model deviance and AIC values indicated that the logistic curve provided the best fit to the data. An additional model run was conducted to determine whether the hypotheses of equal fishing intensity (i.e. the two gears fished equally) were
Output for model runs using the logistic function with the split parameter \((p)\) both held fixed at the expected value based on gear width and with \(p\) being estimated is shown in Table 11. Visual examination of residuals and values of model deviance and AIC indicated that the model with an estimated split parameter provided the best fit to the data. A fitted curve and deviance residuals for the NLCA cruise are shown in Figure 10. Estimated parameters for the final model run are shown in Table 12. For the best model fit as indicated by AIC the estimated \(L_{50}\) value was 105.6 mm and the selection range was 26.7 mm. A final selectivity curve for this data set is shown in Figure 11.

The analysis that estimated the relative efficiency of the two gears based upon the expected and observed split parameter values resulted in an estimated relative efficiency value of 1.334. Assuming the survey dredge operates with 38% efficiency, the expected value for the efficiency of the commercial dredge was 50.7%. These results are lower than those found in Yochum and DuPaul (2008) and suggest a lower efficiency of the CFTDD on this cruise than the 60% efficiency value in the previously calculated estimates of total and exploitable biomass.

In response to concerns from industry related to the product quality of some of the older animals in the NLCA, we qualitatively assessed scallop meats based on color and texture criteria. The phenomenon of “grey meats” is well established as well as stringy meats that tear easily. Based on our observations, the quality of the scallop meats in the NLCA during June was excellent and did not appear to have any detrimental characteristics associated with color or texture issues. We suspect that these issues can be ephemeral and are the result of factors that vary in time and space. This topic merits additional research to not only document its spatial extent and intensity, but to understand the underlying process.

As part of the outreach component of this project, a presentation detailing the results of the survey was compiled. This presentation was delivered to the Sea Scallop Plan Development Team (SSPDT) at their meeting in Falmouth, MA during August 19-20, 2013. Results of this survey were used in the decision making process for Framework Adjustment 25 to the Sea Scallop Fishery Management Plan. The presentation is included as a supporting document to this final report.

**Discussion**

Fine scale surveys of closed areas are an important endeavor. These surveys provide information about subsets of the resource that may not have been subject to intensive sampling by other efforts. Additionally, the timing of industry-based surveys can be tailored to give managers current information to guide important management decisions. This information can
help time access to closed areas and help set Total Allowable Catches (TAC) for the re-
opening. Finally, this type of survey is important in that it involves the stakeholders of the
fishery in the management of the resource.

Our results suggest that for the NLCA sufficient biomass exists to support a limited opening
in 2014 and perhaps 2015. For an area that had been dominated by a large size class, there
appears to have been a large recruitment event in the area and that the age distribution of the
resource is broader relative to prior years. There were a number of remarkable characteristics
related to the observed recruitment event. First, the sheer number of animals caught was
staggering. This is especially impressive given the catchability of scallops of this size (15mm) by
the lined NMFS sea scallop survey dredge is thought to be quite low. Secondly, the spatial
extent of the observed recruitment was interesting in that scallops rarely recruit to the deeper
waters in the South of the access area. Typically, recruitment is in the northern and eastern
portions of the area adjacent to the Great South Channel. We suspect that the observed
recruitment could extend far to the East and West of our sampling and could potentially
represent an impressive year class of recruits in an atypical area of settlement. These pre-
recruits represent an important size class and have the ability to realize year over year
increases in growth as well as the potential to sustain openings in subsequent years and form
the basis for new rotational areas.

The use of commercial scallop vessels in a project of this magnitude presents some
interesting challenges. One such challenge is the use of the commercial gear. This gear is not
designed to be a survey gear; it is designed to be efficient in a commercial setting. The design
of this current experiment however provides insight into the utility of using a commercial gear as
a survey tool. One advantage of the use of this gear is that the catch from this dredge
represents exploitable biomass and no further correction is needed. A disadvantage lies in the
fact that there is very little ability of this gear to detect recruitment events. However, since this
survey is designed to estimate exploitable biomass, this is not a critical issue.

The concurrent use of two different dredge configurations provides a means to not only test
for agreement of results between the two gears, but also simultaneously conduct size selectivity
experiments. In this instance, our experiment provided information regarding a recently
mandated change to the commercial gear (CFTDD). While the expectation was that these
changes should not affect the size selectivity characteristics of the gear (i.e. $L_{50}$ and SR), as
these characteristics are primarily determined by ring and mesh sizes, the possibility exists that
the overall efficiency will be altered by different dredge frame design. Our results differed from
Yochum and DuPaul (2008) with respect to $L_{50}$ and SR. The estimate of $L_{50}$ was higher by
roughly 5 mm. This could be a result of the different underlying length frequency distributions of the population sampled. The estimates only varied by less than 1 cm and were within error of previously reported values. Our estimated p value was lower than what was reported in Yochum and DuPaul (2008). This suggests a lower relative efficiency between the two dredge frames (Yochum and DuPaul (2008) used a New Bedford style dredge frame). These results, while different from other data sets, need to be taken in a broader context that includes different vessels, seasons and geographic regions. Given the major role that dredge efficiency plays in the estimates of biomass from dredge surveys, it is clear that this topic is of critical importance and its refinement should be a high priority.

Biomass estimates are sensitive to other assumptions made about the biological characteristics of the resource; specifically, the use of appropriate shell height:meat weight parameters. Parameters generated from data collected during the course of the study were appropriate for the area and time sampled. There is, however, a large variation in this relationship as a result of many factors. Seasonal and inter-annual variation can result in some of the largest differences in shell height:meat weight values. Traditionally, when the sea scallop undergoes its annual spawning cycle, metabolic energy is directed toward the production of gametes and the somatic tissue of the scallop is still recovering and is at some of their lowest levels relative to shell size (Serchuk and Smolowitz, 1989). While accurately representative for the month of the survey, biomass has the potential to be different relative to other times of the year. For comparative purposes, our results were also shown using the parameters from SARC 50 (NEFSC, 2010). These parameters reflect larger geographic regions (Georges Bank as well as NLCA) and are collected during the summer months. This allowed a comparison of results that may be reflective of some of the variations in biomass due to the fluctuations in the relationship between shell height and adductor muscle weight. Area and time specific shell height:meat weight parameters are another topic that merits consideration.

The survey of the NLCA during June 2013 provided a high-resolution view of the resource in this area. The NLCA is unique in that it has and will continue to play a critical role in the spatial management strategy of the sea scallop resource over the next few years. With the other rotational areas of the mid-Atlantic (Hudson Canyon, Elephant Trunk and DelMarVa) currently closed, the NLCA may have to carry some additional fishing pressure. While these data and subsequent analyses provide an additional source of information on which to base management decisions, it also highlights the need for further refinement of some of the components of industry based surveys. The use of industry based cooperative surveys provides an excellent
mechanism to obtain the vital information to effectively regulate the sea scallop fishery in the context of an area management strategy.

*The length weight relationship for sea scallops from data collected on the cruise is modeled as:

\[ W = \exp(\alpha + \beta \ln(SH)) \]

For SARC 50 (Georges Bank and Northeast Peak) depth is included in the model as follows:

\[ W = \exp(\alpha + \beta \ln(SH) + \gamma \ln(D)) \]

Where \( W \) is meat weight in grams, \( SH \) is scallop shell height in millimeters (measured from the umbo to the ventral margin) and \( D \) is depth in meters.
