Key Points:

- Interior marsh ponds deepen with wider channels connecting the ponds, indicating sediment export through these channels
- Vegetated marshes and ponds occupy alternative stable elevation states, which impairs marsh recovery once converted to open ponds

Abstract Coastal marshes and their valuable ecosystem services are feared to be lost by sea level rise, yet the mechanisms of marsh degradation into ponds and potential recovery are poorly understood. We quantified and analyzed elevations of marsh surfaces and pond bottoms along a marsh loss gradient (Blackwater River, Maryland, USA). Our analyses show that ponds deepen with increasing tidal channel width connecting the ponds to the river, indicating a new feedback mechanism where channels lead to enhanced tidal export of pond bottom material. Pond elevations also decrease with increasing pond size, consistent with previous work identifying a positive feedback between wind wave erosion and pond size. These two positive feedbacks, combined with bimodal elevation distributions and sharp topographic boundaries between interior ponds and the marsh platform, indicate alternative elevation states and imply that marsh loss by pond formation is nearly irreversible once pond deepening exceeds a critical level.

Plain Language Summary Coastal marshes are highly valued ecosystems, but in some areas with increased sea level rise these vegetated marshes disappear and convert into large ponds. Currently, we do not fully understand how these ponds are formed and why marsh vegetation is not recovering in these areas. In this study we measured the soil elevation of marshes and ponds in an area where large marsh surfaces have converted to ponds (Blackwater River, Maryland, USA). We found that ponds are generally deeper when the connection of the ponds with the tidal channels is wider. This indicates that pond sediments can be exported through these channels, and the wider the channel, the easier sediment is exported, leading to deeper ponds. Larger ponds are also deeper because larger waves can develop there, resulting in more wave erosion. These two processes both lead to deeper ponds. Furthermore, we found that there is a sharp elevation drop from the marsh platform into ponds, and that intermediate elevations rarely occur. These all suggest that ponds, once they are formed, are very difficult to recover into marsh vegetation.

1. Introduction

Marsh conversion to interior ponds is considered an important mechanism of coastal marsh loss, particularly where sediment supply and tidal range are very low (e.g., Kearney et al., 1988; Mariotti, 2016; Mariotti & Fagherazzi, 2013; Morton et al., 2003; Penland et al., 2000), with large implications for the loss of highly valued ecosystem services, such as protection against storm impacts (Möller et al., 2014; Stark et al., 2015; Temmerman et al., 2013), nursery habitat for fisheries (Barbier et al., 2011), and storage of soil carbon (Duarte et al., 2013; McLeod et al., 2011).

We hypothesize that marshes and interior open water ponds can be considered alternative stable geomorphic states within the larger coastal marsh ecosystem. This would have the important implication that marsh conversion to ponds is very hard to reverse, as each state is typically sustained by positive feedback mechanisms that provide long-term stability (Moffett & Gorelick, 2016; Scheffer et al., 2001). Marshes have been identified as one stable state of intertidal landforms (Fagherazzi et al., 2006; Marani et al., 2010; van Belzen et al., 2017; Wang & Temmerman, 2013), as they maintain their elevation relative to rising sea level by feedbacks between tidal inundation and accretion of mineral and organic sediments (Kirwan &

Megonigal, 2013; Morris et al., 2002; Temmerman et al., 2004). However, it is unknown if marsh ponds are an alternative, low-elevated state. Previous work suggests that positive feedbacks such as collapse and disintegration of underlying soil organic matter after initial vegetation die-off may reinforce the pond state (Day et al., 2011; Delaune & Pezeshki, 1994; van Huissteden & van de Plassche, 1998). Furthermore, modeling and aerial image analysis suggest that ponds expand by wind wave erosion after they reach a critical size (>200 m, Mariotti, 2016; Ortiz et al., 2017). However, expanding ponds may recover when they intersect a tidal channel and when drainage and sediment infilling promotes the recovery of marsh vegetation (Millette et al., 2010; Perillo et al., 1996; Redfield, 1972; Wilson et al., 2009, 2010). Hence, we do not currently understand whether interior marsh ponds represent an alternative stable state, and we lack field data on elevation changes after marsh conversion to ponds, necessary to understand whether marsh collapse is irreversible.

Here, we report the results of a field study along the Blackwater River marshes (Maryland, USA) where relative sea level rise rates are 3–4 times the global average (Sallenger et al., 2012) and widespread marsh loss is well documented by aerial pictures for about the past century (Schepers et al., 2017). We made measurements of marsh and pond bottom elevation along transects in marshes at five stages of marsh degradation, from intact to completely degraded marshes (Schepers et al., 2017). We identify sediment export through connecting channels as a new mechanism for pond deepening and show that topographic characteristics of marshes and ponds are consistent with alternative states, suggesting that reversal of pond expansion is unlikely in these rapidly deteriorating marshes.

2. Methods

2.1. Study Area

The Blackwater marshes ($38^{\circ}24'N$, $76^{\circ}40'W$, supporting information Figure S1) are organogenic, microtidal marshes that discharge into Fishing Bay, an embayment of the Chesapeake Bay. Previous research showed that the marshes are being converted to open water ponds at least since the 1930s (Schepers et al., 2017). There is a spatial gradient in marsh loss from intact marshes close to Fishing Bay, to increasing pond surface area with increasing distance upstream the Blackwater River up to Lake Blackwater, a vast open water area that consisted of marshes back in the 1930s (Figures 1 and S2). Marsh loss has been attributed to insufficient surface accretion (on average $1.7\text{--}3.6$ mm yr^{-1} ; Stevenson et al., 1985) compared to relative sea level rise (currently 3.83 mm yr^{-1} nearby in Cambridge, MD, NOAA station 8571892, <http://tidesandcurrents.noaa.gov/sltrends>, 2 May 2020), disturbance by invasive Nutria (*Myocastor coypus*) (Kendrot, 2011; Stevenson et al., 1985), and lateral erosion of the ponds (Ganju et al., 2013; Stevenson et al., 1985).

2.2. Soil Elevation Measurements

We selected five field sites along the marsh loss gradient (Schepers et al., 2020; Figure S1). At each field site, three parallel marsh transects of 1,000 m length (each 250 m apart) that straddle the Blackwater River were generated, and points were selected with a 10 m interval along the transects by using a geographic information system (GIS) (ArcGIS 10.3, ESRI). We located each point in the field in the summer of 2014 and recorded the elevation relative to the North American Vertical Datum of 1988 (NAVD88) with a high-precision GPS (Trimble R8 RTK-GPS, vertical error <2 cm, at Site 5 vertical error <4.5 cm). Points located in tidal channels were not included in the analyses. At the degraded Site 5, points located in the 1938 channel were also excluded. For each site, the NAVD88 elevations were recalculated to local mean sea level as measured by water level loggers. The nonparametric Wilcoxon rank sum statistic (Mann-Whitney U) was used to test the elevation differences between marshes and ponds for each field site ($\alpha = 0.05$).

Additional topographic measurements were performed at the transitions from vegetated marshes to unvegetated pond areas. At these transitions, we measured two points on the vegetated marsh platform, one as close as possible to the pond edge and still in the marsh vegetation, and one point approximately 1 m from the pond edge. Similarly, two elevation points were recorded in the unvegetated pond areas, one as close as possible to the pond edge and one approximately 1 m from the pond edge in the pond. Horizontal distances between these points were calculated from the point coordinates (horizontal error <2 cm), and subsequently the slope (elevation change divided by horizontal distance) was calculated in between subsequent marsh

Figure 1. Elevation distribution of marsh (gray) and pond (black) points (marsh areas that converted to bare patches or open water without vegetation) for the five field sites (1–5) with increasing vegetation loss in upstream direction along the Blackwater River. Histogram bin width is 0.025 m. Inundation time (in %) quartiles are visualized as blue vertical lines; the average semidiurnal tidal range is visualized as a light blue rectangle. Aerial images of the sites are visualized on the right, with reddish colors representative for marsh vegetation and darker areas for open water.

points, pond points, and for the transition from marshes to ponds. The slope differences between these three morphological units were tested with the nonparametric pairwise Wilcoxon rank sum test with Bonferroni correction ($\alpha = 0.05$).

2.3. Water Level Measurements

Water levels were measured every 15 min at each field site from 14 August to 29 October 2014. Pressure transducers (Hobo U20L-02, Onset, MA, USA) were deployed in a PVC (polyvinylchloride) stilling tube at the river bank, and the elevation of each sensor was recorded with a high-precision GPS (see previous paragraph) to refer the water level data to the NAVD88 vertical datum after local atmospheric pressure compensation. Tidal characteristics (including mean high water level, mean low water level, mean semidiurnal tidal range, and relation between elevation and inundation time [in %]) for each field site were calculated with the Tides package in R (Cox & Schepers, 2017).

2.4. Environmental Variables as Potential Controls on Soil Elevation

We studied the influence of several environmental variables on marsh surface elevation and pond bottom elevation derived from an aerial image of 2010 classified into vegetated marsh areas, ponds, and the Blackwater River (Schepers et al., 2017). To examine how marsh and pond elevations varied along the marsh loss gradient, we calculated the river length from the middle of each field site to the mouth of the Blackwater

River. This variable accounts for several potential large-scale environmental differences between the field sites such as differences in tidal range and sediment availability, which both are known to decrease with increasing upstream distance along the Blackwater river (Ganju et al., 2013; for tidal range see previous section).

To test if marsh surface elevation is related to distance from open water, we calculated the Euclidean distance of each marsh point to the Blackwater River, to secondary channels that are directly connected with the Blackwater River, and to inner marsh ponds.

To test if pond bottom elevation is related to the degree of connectivity between the pond and the Blackwater River, we measured the minimum width of the channel connecting each pond with the Blackwater River and the distance to the Blackwater River. The minimum width for each connecting channel was calculated as the double of the minimum distance from the centerline (the middle of the connecting channel) to the channel banks. Ponds that were not connected received a value of 0. The connection distance was defined as the minimum travel distance from each pond point to the Blackwater River along secondary channels or water bodies. To include unconnected ponds in the analysis, the connection distance was categorized in four classes: not connected, connection <2,000 m, connection 2,000–4,000 m, and connection >4,000 m. These connected classes coincide with three modes in the distance distribution.

To study the potential effect of waves on pond bottom elevation, we calculated the distance of each pond point to the nearest vegetated marsh and estimated the wind fetch length. The latter is defined here as the length of a line that covers a continuous water surface from one side of the pond to the other. This was determined in four directions and averaged for each pond point (Scheepers et al., 2017).

Finally, we tested the effect of pond age on pond bottom elevation. We defined the minimum age of the pond points based on aerial images of 1938, 1981, 1995, 2006, 2010, and 2013. Our fieldwork was carried out in 2014, so the minimum age is 2014 subtracted by the year of the earliest aerial image on which the point was located in a pond.

2.5. Statistical Analyses

To test which environmental variables (see previous section) significantly influence the soil elevation, we fitted a linear regression model to explain the elevation of the vegetated marsh platform using 916 marsh elevation points. We started the marsh model selection with four calculated variables: (1) downstream river length to the river mouth, (2) the Euclidean distance to the Blackwater River, (3) distance to secondary channels that are directly connected with the Blackwater River, and (4) distance to inner marsh ponds. A second model was fitted with 692 pond points to explain the pond bottom elevations. The mean fetch length variable was omitted to avoid collinearity with distance to the nearest marsh. We started the pond model with five variables: (1) downstream river length to the river mouth, (2) the (log) distance to the nearest marsh, (3) minimum width and (4) length of connecting channel, and (5) the minimum pond age. Each of the two models started with all the variables, followed by a backward model selection until only significant variables were present in the model (Zuur et al., 2009); see Text S1. All statistics were performed in R, version 3.2.2 (R Core Team, 2017).

We performed random forest analyses to validate the results of both linear regression models (see supporting information).

3. Results

3.1. Indications for the Existence of Alternative Elevation States

Several indicators, including bimodality of the elevation distribution and sharp elevation transitions between one state and the other, both in space and time, point to alternative state behavior of marshes and ponds.

A bimodal distribution of a key environmental variable can be an indicator of alternative stable states, with each mode focusing around the equilibrium values that characterize each state (Scheffer & Carpenter, 2003; Schröder et al., 2005). The elevation measurements have a bimodal distribution with different marsh and open water pond elevations (Figure 1). At Field Site 1, with almost intact marshes and very few ponds,

the marsh has a clear unimodal elevation distribution around 0.25 m relative to mean sea level. At Field Sites 2–5, which represent a gradient of increasing marsh loss and hence an increasing proportion of pond data (Table S1) and pond area (Scheepers et al., 2017), the pond elevations are decreasing compared to the marshes. This results in a bimodal elevation distribution, characterized by the separation of the elevation distributions of higher elevation, vegetated marshes from low elevation, unvegetated ponds, and a low occurrence of intermediate elevations (Figure 1). At all field sites, including the most intact, the ponds and marshes occupied a significantly different elevation ($p < 0.001$). However, it seems that an equilibrium elevation in the ponds has only been reached at Field Site 5, Lake Blackwater, which has a mode at 1.2 m below mean sea level.

Another potential indicator of alternative stable states is a sharp spatial boundary between contrasting sites (Scheffer & Carpenter, 2003; Schröder et al., 2005). The transitions from the marsh platform to the pond bottom are steep (Figure 2), with slopes typically exceeding 0.5. In contrast, slopes within the marshes and ponds are more gradual (typically ~ 0.01) and not statistically different from each other (Figure 2). Steep transitions or cliffs are also observed at marsh-tidal flat borders in other areas and interpreted there as indicative of bistable states (van de Koppel et al., 2005). In our study area, the pond cliffs probably emerge from the different feedback mechanisms between marshes and ponds: It is known that marshes maintain high elevations in the tidal frame by capturing sediment or building up organic matter (Baustian et al., 2012; Mudd et al., 2010; Temmerman et al., 2012). But ponds lacking the vegetation-induced sedimentation feedback are unable to capture sediment and deepen by the collapse of the soil and root structure (Day et al., 2011; Delaune & Pezeshki, 1994; van Huissteden & van de Plassche, 1998), thus increasing the elevation deficit between marshes and ponds.

Our analyses did not identify the minimum age of ponds as a significant explanatory variable explaining pond depth (Figure 3, right, Table S3, and Figure S4). This suggests that pond deepening is not a gradual process that continues at a steady rate. Maximum pond depths for the different pond age classes increased from pond ages of 4 to 33 years and remained similar for pond ages between 33 and 76 years (Figure 3, right). This suggests that pond depths can reach a maximum (close to -1.5 m) in a relatively short time (~ 33 years) after which deepening with time is minimal. It corroborates with our above discussed indicators of alternative stable states, as state shifts would occur relatively rapidly until a new stable state is reached (Scheffer & Carpenter, 2003; Schröder et al., 2005; Wang & Temmerman, 2013).

Bimodality of the elevation distribution, steep cliffs, and the relatively quick deepening of marsh elevation to interior ponds suggest alternative state behavior. In addition, our analyses demonstrate that the elevation of marshes and interior ponds is sustained by different factors and feedback mechanisms. Marshes maintain high elevations in the tidal frame by capturing sediment from the water column. This is evident as marsh elevations decrease upstream and with increasing distance from the Blackwater River, reflecting gradients in tidal range and sediment availability (Text S1 and Tables S1 and S2) (Christiansen et al., 2000; Friedrichs & Perry, 2001; Ganju et al., 2015; Moskalski & Sommerfield, 2012; Temmerman et al., 2003). However, pond elevations are linked to erosion and sediment export (see next paragraphs). Consequently, this suggests that marshes and interior ponds represent different stable elevation states.

3.2. Ponds Deepen With Increasing Pond Size and Wider Connections to the Tidal Channel System

Little is known about the factors influencing pond depth. Here we demonstrate that pond depth increases with pond size and wider connections to the tidal channel system and that these factors are linked to erosion and sediment export.

As a general pattern, pond elevation measurements demonstrate that the elevation decreases with increasing marsh loss and hence increasing total pond surface area. The average pond elevation decreases from -0.41 to -0.52 m between Field Sites 2 to 4 and further to -0.96 m at Field Site 5 (Figure 1), where marshes have completely converted to open water (Figure S2). Our statistical model indicates that the distance of points to the nearest marsh edge and the minimum width of channels connecting the ponds to the tidal channel network are the two statistically significant variables explaining the variations in pond bottom elevation (Figure 3 and Table S3). Other factors, including downstream distance to river mouth, length of

Figure 2. The elevation differences in marshes or ponds are significantly more gentle than at the transition between the two states, as shown in boxplots of the slopes within marshes, the transition from marshes to ponds, and within ponds for Sites 1–4. Within each site, significantly different slopes are labeled with different letters (pairwise Wilcoxon rank sum test with Bonferroni correction, $\alpha = 0.05$). At the transitions of Site 3, two points with slope 2.8 and 6.8 are not visible on the figure.

connecting channel, and the minimum pond age did not have a significant effect on pond bottom elevation. These results are supported by the random forest analysis (Text S1 and Figure S4).

The relationship between pond bottom elevation and distance to marsh (Figure 3, left) shows that small ponds have shallow depths and that larger ponds have depths that logarithmically increase with distance from the nearest marsh edge, such that the sharpest increase in pond depth occurs at a short distance from the marsh edge. The distance to the marsh edge is highly correlated with the mean fetch length (Pearson's r : 0.86), which is an important factor influencing wind wave erosion on tidal flats (Carniello et al., 2009; Fagherazzi et al., 2006; Mariotti & Fagherazzi, 2013) and which suggests that as ponds expand over time, they become increasingly susceptible to pond bottom deepening by wind waves. Previous studies identified a critical interior marsh pond size of 200–1,000 m for wave-induced erosion of vegetated pond edges (Mariotti, 2016; Ortiz et al., 2017). The majority of the ponds in our study are smaller than this critical size (Table S1). The bottom of ponds typically consists of very weak, liquefied material that is expected to be much easier eroded than vegetated pond edges, and hence wave-induced erosion of pond bottom material

Figure 3. Pond bottom elevation (in m relative to mean sea level) with distance (logarithmically transformed) to the nearest marsh (left), the minimum width of the channel connecting ponds to the tidal channel network (middle), and minimum pond age (right figure). Multiple linear regression analysis (supporting information and Table S3) revealed that the distance to the marsh and the minimum width are significantly related to pond depth; minimum age was not significant.

Figure 4. Conceptual model of subsequent stages and mechanisms of pond bottom deepening.

occurs in ponds that are smaller than the critical pond size for pond edge erosion (Schepers, 2017; Stevenson et al., 1985).

We identify the connection of ponds to the tidal channel system as a new important mechanism for exporting sediments from ponds, as we find that ponds get deeper with wider connecting channels (Figure 3, middle; and conceptual model in Figure 4). The width of connecting channels is controlled by pond size (Pearson's r : 0.89) as larger ponds have a larger tidal prism (i.e., larger tidal volumes flooding and draining from the ponds) and marsh channels that convey a larger tidal prism are known to develop larger channel widths (D'Alpaos et al., 2010; Rinaldo et al., 1999; Vandenbruwaene et al., 2013). Previous measurements in our study area indicate that tidal currents cause net sediment export via the channel system and that this is maximized during northwesterly wind events, which corresponds with the orientation of ponds, suggesting that pond erosion is the dominant contributor to the sediment export (Ganju et al., 2013; Stevenson et al., 1985). Across eight microtidal sites along the U.S. Atlantic and Pacific coasts, including our study area, a larger pond-to-marsh surface ratio correlates with larger sediment export through the channels (Ganju et al., 2017). These all indicate that ponds are major source areas of sediments that are exported by tidal currents via the channel system. Although we have no direct observations of tidal currents and sediment transport in the ponds themselves, pond bottoms typically consist of very loose, liquefied soil material that is easily suspended and exported by tidal currents via the channels connected to ponds (Stevenson et al., 1985). The wider the connecting channel, the lower the pond bottom elevation (Figure 3, middle), suggesting that export is facilitated when connecting channels are wider. Wider channels are generally also deeper (e.g., D'Alpaos et al., 2010; Vandenbruwaene et al., 2013), which would imply lower bottom friction and would enable

stronger tidal currents and larger sediment export. Resuspension and export of loose pond bottom material close to the pond edge would steepen the pond-marsh transition and make the pond edge more susceptible for slumping (e.g., Mariotti et al., 2016; Stevenson et al., 1985). As such export of pond sediments may contribute to further pond expansion as well as deepening (see conceptual model in Figure 4).

The mechanism of pond deepening and expansion driven by tidal connections adds to previous work that focused on wind-driven erosion as the primary mechanism of pond expansion (Mariotti & Fagherazzi, 2013; Ortiz et al., 2017). Previous studies show that a connection with the tidal channel system drains ponds and thereby enables plant reestablishment, followed by fast sediment accretion (Millette et al., 2010; Perillo et al., 1996; Redfield, 1972; C. A. Wilson et al., 2014; K. R. Wilson et al., 2009, 2010). Channel-driven pond expansion and permanent marsh loss in our Field Sites 2–5 (Schepers et al., 2017; Stevenson et al., 1985) seem contradictory to these studies. We suggest the low tidal range of our site as a potential explanation for the different behavior, where a relatively small loss in elevation results in a large increase of tidal inundation time and hence increased stress for plant reestablishment (Kearney & Turner, 2016; Kirwan & Guntenspergen, 2010).

While our study highlights feedback mechanisms between pond bottom erosion, pond size, and pond connection to the channel network, little is known on how initially small and unconnected ponds deepen and expand, that is, before the identified feedback mechanisms start to play a role. It has been suggested that biochemical decomposition of the organic material at the bottom and edges of the ponds is the main driver of initial pond deepening and expansion (DeLaune et al., 1994; van Huissteden & van de Plassche, 1998). The fact that pond age is not a significant factor determining pond depth, also when only small (<100 m) unconnected ponds are included in the regression model analysis (results not shown), suggests that the early stages of pond deepening do not occur gradually with time. Hence, identifying the drivers of initial pond deepening and expansion is an unresolved issue that merits further research.
