This Dissertation is brought to you for free and open access by the Theses, Dissertations, & Master Projects at W&M ScholarWorks. It has been accepted for inclusion in Dissertations, Theses, and Masters Projects by an authorized administrator of W&M ScholarWorks. For more information, please contact scholarworks@wm.edu.
INFORMATION TO USERS

This manuscript has been reproduced from the microfilm master. UMI films the text directly from the original or copy submitted. Thus, some thesis and dissertation copies are in typewriter face, while others may be from any type of computer printer.

The quality of this reproduction is dependent upon the quality of the copy submitted. Broken or indistinct print, colored or poor quality illustrations and photographs, print bleedthrough, substandard margins, and improper alignment can adversely affect reproduction.

In the unlikely event that the author did not send UMI a complete manuscript and there are missing pages, these will be noted. Also, if unauthorized copyright material had to be removed, a note will indicate the deletion.

Oversize materials (e.g., maps, drawings, charts) are reproduced by sectioning the original, beginning at the upper left-hand comer and continuing from left to right in equal sections with small overlaps.

Photographs included in the original manuscript have been reproduced xerographically in this copy. Higher quality 6" x 9" black and white photographic prints are available for any photographs or illustrations appearing in this copy for an additional charge. Contact UMI directly to order.

Monitoring a program's execution is fundamental to the debugging, testing and maintenance phases of program development. This research addresses the issue of monitoring the execution of a distributed program. In particular, we are concerned with efficient techniques for evaluating global state predicates for distributed programs. The global state of a distributed program is not well-defined, making the monitoring task complex compared to that of a sequential programs. Processes of a distributed program execute concurrently, and the events of the program cannot be totally ordered. Each process has its own local memory, and the local memories are physically separate.

Despite the difficulties of defining a distributed computation's states, monitoring a distributed program requires reasoning about constituent processes' execution as a single collective entity. We have extrapolated the semantics of the sequential program's assert statement into the distributed context. A distributed assert statement is a global predicate that is anchored at a control point of one processes, and that is evaluated when that process executes the assert.

We have developed a runtime method for monitoring both stable and unstable properties that does not disrupt the computation of the distributed system. A distributed assert statement is evaluated with that statement's causal global state which incorporates the state of the system as a whole as it may have causal impact upon the assert statement. A runtime protocol has been implemented that constructs the causal global state and evaluates the assert statement. No additional synchronization or message passing is imposed on the distributed application although some message sizes are increased to propagate state information. The causal global state is immediately available providing real-time feedback.
CAUSAL DISTRIBUTED ASSERT STATEMENTS
Chapter 1

Introduction

1.1 Monitoring Sequential Programs

Observing a program’s execution is fundamental to the debugging, testing and maintenance phases of program development. Debugging is premised on the ability to examine the value of a variable at chosen points during the execution of a program. Testing involves detecting erroneous threads of execution and invalid variable values. Maintenance relies on the ability to follow a program’s execution and detect deviations from anticipated behavior.

The ability to observe a sequential program’s execution is straightforward since a single thread of execution defines a total temporal order on the program’s atomic operations. The execution of each atomic operation results in a new program state, where a program state is a function from variables to values [12]. An ordered sequence of states is defined while the program is executing, and at any point of execution the state of the program is immediately available since all variable values are stored in the same local memory.
Debugging, testing and maintenance examine a program’s execution by comparing states with expected behavior. One common method of conveying the expected behavior of a program utilizes state predicates. A predicate used in this manner is a boolean function on a program state and is evaluated by replacing variables of the predicate with their state values [12]. Predicate evaluation is straightforward in a sequential program since a state is well-defined and immediately available.

Choosing appropriate predicates is dependent on the application and the activities monitored. Predicates can be chosen to detect program malfunction and, if skillfully designed, relay a strong clue about the location of the bug leading to the failure. Particular points of a program’s execution may be crucial, and predicates should be designed for evaluation at these points. Evaluating a predicate after the execution of an identified atomic operation is consistent with Hoare-style axiomatic program verification techniques [14]. Complex verification statements such as loop invariants, upon which a proof of partial correctness is usually hinged, make obvious candidates for conversion into predicates. Debugging breakpoints and diagnostic print statements indicate positions for developing appropriate predicates. Independent of the application, predicates are a powerful monitoring tool throughout the program’s life cycle.

1.2 Monitoring Distributed Systems

This research addresses the issue of monitoring the execution of a distributed program. In particular, we are concerned with efficient techniques for evaluating global state predicates for distributed programs. The global state of a distributed program is not well-defined,
making the task of monitoring complex compared to sequential programs. Processes of a
distributed program execute concurrently, and the events of the program cannot be totally
ordered. Each process has its own local memory, and the local memories are physically
separate from one another. A process is only immediately aware of its own local state.
Access to the state of a remote process requires communication and incurs a delay which is
usually substantial and often unpredictable.

1.2.1 System Model

A sequential program's execution and the execution of a single process of a distributed pro-
gram are similar. The $i^{th}$ atomic operation or event of a sequential program is represented
by $e_i$, and the resulting state is represented by $S_i$. The execution of a sequential program
is modeled as

$$\sigma = S_0 \xrightarrow{e_1} S_1 \xrightarrow{e_2} S_2 \ldots$$

The notation $S_{i-1} \xrightarrow{e_i} S_i$ denotes the execution of event $e_i$ which causes a transition from
state $S_{i-1}$ to $S_i$.

A distributed system consists of a fixed number of distinct processes $\Pi = \{P_0, \ldots, P_{N-1}\}$.
These processes share no memory and interact only via message passing. Each process con-
sists of a totally ordered sequence of atomic events. The $i^{th}$ event of $P_j$ is represented by
$e^j_i$, and the resulting local state is represented by $S^j_i$. The execution of $P_j$ is modeled as

$$\sigma/j = S^0_j \xrightarrow{e^j_1} S^1_j \xrightarrow{e^j_2} S^2_j \ldots$$
In both a process and a sequential program, it is possible to say which event or state happened before another event or state since the events of both are totally ordered. The execution of a distributed program is viewed as a set of events $E = E_0 \cup \cdots \cup E_{N-1}$ where $E_i$ represents the events of $P_i$, and an irreflexive partial order is defined on these events [19]:

$$\rightarrow \subseteq E \times E.$$  

The $\rightarrow$ relation is commonly referred to as happened before. For $e, f \in E$, $e \rightarrow f$ if and only if $e$ has potential causal impact upon $f$.

### 1.3 The Happens Before Relation

Interprocess communication defines the happens before relationship among events on different processes. Asynchronous communication occurs when a process places a message "on the network," and continues execution. The process receiving the message blocks until it receives the message, then continues execution.

In an asynchronous communication regime, $\rightarrow$ is the smallest relation satisfying the following three conditions: (1) if $e$ and $f$ are events in the same process, and $e$ happens before $f$, then $e \rightarrow f$; (2) if $e$ is the sending of a message and $f$ is the receipt of the same message, then $e \rightarrow f$; and (3) if $e \rightarrow f$ and $f \rightarrow g$, then $e \rightarrow g$.

If $e \rightarrow f$, we say that $e$ causally precedes $f$ and that $f$ causally succeeds $e$. If $e \not\rightarrow f$ and $f \not\rightarrow e$, then we say that $e$ and $f$ are causally unrelated or concurrent, denoted $e \parallel f$, and neither can causally affect the other.
1.3.1 Asynchronous Message Passing Library

We have developed a library of asynchronous communication functions for writing distributed programs that communicate asynchronously. Each process's program is written in the programming language C[16] with the addition of the asynchronous communication functions for message passing between processes. Appendix B covers in detail the asynchronous functions, but the two of primary interest are `async_send` and `async_recv`. The function `async_send` has the following format:

```
async_send(i, msg, len).
```

The message pointed to by `msg` of length `len` is sent to process `i`. If `i` is `-1`, the message is broadcast to all the processes of the distributed program. The function `async_recv` has the following format:

```
async_recv(i, msg, len, waitsecs).
```

A message from process `i` is copied into the address `msg`. The length of the received message is `len`. If a message does not arrive within `waitsecs`, `async_recv` returns with a value of `-1`. If `i` is `-1`, the message is accepted from any process of the distributed program. If `waitsecs` is 0, the process waits until the message is received. When presenting example programs, only the fields of `i` and `msg` for both `async_send` and `async_recv` will be indicated. The field `waitsecs` of `async_recv` is assumed to be 0 unless otherwise indicated.

The asynchronous library routines implement reliable FIFO (First In First Out) communication by default. Unreliable or non-FIFO communication can be configured by functions
described in the appendix. The example asynchronous distributed programs that appear in this document are based on reliable and FIFO communication unless specified otherwise.

1.3.2 Partial Order of Events

When a distributed program executes, a partial order of the program events is defined. The order is not total because some events on different processes are causally unrelated. Figure 1.1 is a distributed program of two asynchronously communicating processes. The dots denote statements that are not relevant to the communication. A time-space diagram of the program's execution is given in figure 1.2. Each vertical line corresponds to a process's execution where the direction of the line indicates time increasing, and each tick on that execution line corresponds to an event. A diagonal arrow between two processes denotes a communication. The following are some of the concurrent (||) and causal (→) relationships that exist between the program's events:

<table>

</tr>
</tbody>
</table>

1.3.3 Multiple Partial Orders

The communication of a distributed program is classified as defining either a single partial order or multiple partial orders. The classification is based on the control constructs and
CHAPTER 1. INTRODUCTION

Figure 1.1: Asynchronous program

...}

Figure 1.2: Space-time diagram

the communication functions they affect. The remaining statements of a process do not affect the partial order. and therefore are ignored.

If none of the processes have control constructs affecting the communication functions, the classification is a single partial order. If one or more of the processes have a control construct selecting among multiple communication functions, the classification is multiple partial orders. The partial order defined when the distributed program executes may differ according to which communication function is selected by the control construct.

Figure 1.3 is an example of a distributed program that is classified as defining multiple partial orders. The if/else control construct of $P_0$ selects one of the two groups of communications functions to execute. The two possible partial orders are shown in figure 1.4. The function $async.send(1,w)$ is represented by $i$. function $async.send(2,w)$ is presented by $j$. function $async.recv(0,y)$ is represented by $k$. and function $async.recv(0,z)$ is represented by $l$.

1.4 Outline of the Dissertation

Chapter two presents several distributed programs that will be used in discussing distributed monitoring methods. The programs range from a single partial order program with repeating communication patterns to a multiple partial orders program with complex communication patterns.

In chapter three we review well-known monitoring methods that appear in the literature. Problems that these monitoring methods incur are discussed. Both runtime and postmortem methods are reviewed.
In chapter four our methodology for monitoring a distributed system is presented. The terminology and notation corresponding to our methodology is defined. This chapter also contains our initial algorithms.

Chapter five examines the affects of our initial algorithm to the execution of a distributed program and defines the messages that are sufficient for implementing our method of monitoring a distributed system. Chapters six and seven present algorithms for optimizing our initial results.

In chapter eight we apply our methodology for examining the execution of a distributed program to the programs of chapter two. Chapter nine concludes with possible avenues for continuing our research.
Chapter 2

Distributed Programs

Five distributed programs appear throughout this document to demonstrate and clarify concepts for monitoring distributed programs. These programs are described in detail in this chapter. The communication complexity of the programs varies greatly and is discussed with each program.

2.1 Set partition

SETPART, the set partition program, by Dijkstra [7] partitions disjoint integer sets $S$ and $T$. SETPART exchanges an element of $S$ with an element of $T$ until the elements of $S$ are less than the elements of $T$. The original sizes of $S$ and $T$ are maintained after each exchange. SETPART consists of two distributed processes, $P_0$ and $P_1$. $P_0$ maintains $S$ and $P_1$ maintains $T$. Processes $P_0$ and $P_1$ exchange an integer to determine if the sets are already partitioned correctly, then $P_0$ initiates an integer exchange with $P_1$ if there exists an element of $S$ that is greater than the element previously received from $P_1$. For the exchange, $P_0$ sends the maximum element of $S$ to $P_1$ and removes this value from its set.
$P_1$ receives the integer from $P_0$ and adds this integer to $T$. Then $P_1$ sends the minimum element of $T$ to $P_0$ and removes this minimum value from its set $T$. $P_0$ receives the integer from $P_1$ and adds this integer to $S$. $P_0$ continues to initiate an exchange until it determines that the sets are partitioned correctly. If the last value $P_0$ receives from $P_1$ is greater than or equal to the maximum of $S$, then no element of $T$ is less than any element of $S$. And $P_0$ can conclude that partitioning is complete.

Set Partitioning's communication behavior exhibits *conversational continuity* [31], which is interactive communication between processes where a continuously repeating communication pattern is formed. The number of communications between the SETPART processes is dependent on the input data, but the communication pattern is static. Figure 2.1 is the distributed SETPART program for $P_0$ and $P_1$. The function $\text{max}$ returns the maximum integer of the operand set, and the function $\text{min}$ returns the minimum integer of the operand set.

```
$P_0::$
1  mx = max(S)
2  async_send(1, mx)
3  S = S - {mx}
4  async_recv(1, x)
5  S = S U {x}
6  mx = max(S)
7  while (mx > x)
8     async_send(1, mx)
9     S = S - {mx}
10    async_recv(1, x)
11    S = S U {x}
12    mx = max(S)
13  endwhile

$P_1::$
14  while(true)
15    async_recv(0, y)
16    T = T U {y}
17    mn = min(T)
18    async_send(0, mn)
19    T = T - {mn}
20  endwhile
```

*Figure 2.1: Algorithm for Set Partitioning Program*
2.2 Mutual Exclusion

The circulating token mutual exclusion protocol can be embedded in distributed processes' application code if global mutual exclusion control is needed. The protocol defines a logical cycle through the processes, and the communication pattern is not influenced by the distributed system's application.

P(i): do
   1     async_recv((i + N - 1) mod N. token. waitsecs)
   2     if message received
   3       if want.cs_i
   4         in.cs_i=true: critsec_i; want.cs_i=false
   5       endif
   6     async.send(((i + 1)mod N).token)
   7     else /* async_recv timed out */
   8       do_other_i
   9     endif
  10 enddo

Figure 2.2: MUTEX

MUTEX [21], shown in figure 2.2, is a token-based protocol for administering mutual exclusive critical section entry for a distributed system of N processes. The protocol allows only one process to enter its critical section at a time. Only one token exists in the system, and a process can neither create a token nor destroy the token. The processes are responsible for circulating the token around the system so that every process eventually receives the token. Process P_i receives the token from P_{((i+N-1)modN)} and sends the token to P_{((i+1)modN)}. A process indicates that it wants to enter its critical section by setting want.cs to true. A process only enters its critical section when it receives the token and want.cs is true. Immediately before the process enters its critical section, in.cs is set to
true. Process $P_i$ passes the token to its neighbor $P_{(i+1) \mod N}$ either when $P_i$ completes its critical section or when $P_i$ does not want to enter its critical section.

### 2.3 Bubble Sort

This distributed bubble sort algorithm is based on the odd-even transposition variation of the sequential bubble sort [43]. A total of $q$ integers are sorted in ascending order with $N$ processes where $N < q$. The processes are connected in a logical ring so that $P_i$'s neighbors are $P_{i-1}$ and $P_{i+1}$. Initially each process is assigned a list of $q/N$ elements, and each list is sorted locally using a sequential sort.

The distributed sort consists of $N$ phases, numbered 0 to $N - 1$. If the phase number is even, each even numbered process sends its sorted list to its higher numbered odd neighbor, and each odd numbered process sends its sorted list to its lower numbered even neighbor. Each process merges the received list with its own list and sorts the resulting list. Each odd numbered process retains the last $q/N$ elements of the list as its sorted list, and each even numbered process retains the first $q/N$ elements of the list as its sorted list.

If the phase number is odd, similar steps are followed as for an even phase number. Each odd numbered process sends its sorted list to its higher numbered even neighbor, and each even numbered process sends its sorted list to its lower numbered odd neighbor. Each process merges the received list with its own list and sorts the resulting list. Each even numbered process retains the last $q/N$ elements of the list as its sorted list, and each odd numbered process retains the first $q/N$ elements of the list as its sorted list. Processes 0
and $N - 1$ do not participate in odd numbered phases.

After $N$ phases are complete, all $q$ numbers are sorted in ascending order where $P_i$ has the elements $i \times q/N$ through $(i+1) \times q/N - 1$ of the sorted list. The bubble sort algorithm is shown in figures 2.3 and 2.4. Figure 2.5 shows the communication pattern for a bubble sort with a six process distributed system.

$$P_i::$$

```
integer pid, phase;
arrays list, recv_list
1 pid = process's id
2 read $q/N$ elements into list
3 sort list
4 for phase = 0 to $N - 1$
5   if phase is even
6      if pid is even
7         async_send(pid + 1, list)
8         async_recv(pid + 1, recv_list)
9         list = merge_sort(list, recv_list, first)
10     else
11        async_send(pid - 1, list)
12        async_recv(pid - 1, recv_list)
13        list = merge_sort(list, recv_list, last)
14   endif
15 endif
16 if phase is odd && pid != 0 && pid != $N - 1$
17   if pid is even
18      async_send(pid - 1, list)
19      async_recv(pid - 1, recv_list)
20     list = merge_sort(list, recv_list, last)
21   else
22      async_send(pid + 1, list)
23      async_recv(pid + 1, recv_list)
24     list = merge_sort(list, recv_list, first)
25   endif
26 endif
27 endfor
```

1    merge_list = merging of recv_list and list
2    sort merge_list
3    if half = first
4        return first half of elements in merge_list
5    else
6        return last half of elements in merge_list
7    endif

Figure 2.4: Local Sort

Figure 2.5: Distributed Bubble Sort

2.4 Tree Sort

The $N$ processes of the tree sort distributed program are arranged in a binary tree. The number of processes required for this sort is $2^p - 1$, where $p > 1$. $2^{p-1}$ processes are leaf nodes. The process which is the root node of the tree initiates the sorting of $q$ numbers, $q > N$. The root process splits the list in half and sends one half to each child process. If the receiving child process is not a leaf, it repeats the same steps as the root process. If the

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
number of elements in the list is odd, the left child receives one more element than the right child. If the receiving child process is a leaf node, it sorts the list and sends the sorted list to its parent process. Once a parent process has received both of its children’s sorted lists, the parent merges the two lists into one sorted list. If the parent node is not the root node, it sends this sorted list to its parent. The sort is complete when the root node receives two sorted lists from its children, and merges the two into one sorted list of \( q \) numbers.

The tree sort algorithm is shown in figure 2.6. Figure 2.7 is the binary tree formed by 15 processes (\( p = 4 \)) \( P_0 \ldots P_{14} \), and figure 2.8 shows the tree sort for the 15 processes.

2.5 Positive Ack/Retrans Protocol

The positive acknowledgement/retransmission protocol presented by Tannenbaum [41] enforces reliable communication between two communication nodes, $CN_s$ and $CN_r$, on an unreliable physical transmission line. The communication node $CN_s$ only sends data messages, and the communication node $CN_r$ only receives data messages. Associated with $CN_s$ is at least one host that supplies the data for the outgoing messages, and associated with $CN_r$ is at least one host that consumes the data of the incoming messages. Once $CN_s$ has transmitted a message, it does not send another message until the message is received by $CN_r$ without errors. The node $CN_r$ informs $CN_s$ with an acknowledgement message when it has received a message without errors. If $CN_s$ does not receive an acknowledgement within a predetermined amount of time, it retransmits the data message.

Since the communication line is unreliable, the data message and the acknowledgement message can be lost or corrupted. There exists a problem with retransmitting the data message when the acknowledgement message is lost. Suppose $CN_r$ has received an uncor-
rupted data message and sends an acknowledgement. If the acknowledgement is lost, \( CN_s \) retransmit the same data message. The node \( CN_r \) does not realize the data message is being retransmitted and interrupts the retransmitted message as a new message.

One bit appended to the data message provides the information for the receiver to distinguish between a retransmitted message and a new message. The node \( CN_s \) maintains a bit by alternating the bit when it receives an acknowledgement and appends the current value of the bit on data messages. The node \( CN_r \) maintains a bit by alternating the bit when it receives a valid data message. The receiver only accepts a data message as a new message if the bit on the message matches its bit value. Following is the described protocol:
**Procedure** $CN_s$::

Procedures:

```
1. **MsgBitSend**: bit /* alternating bit */
   sbuffer: message /* buffer for outgoing data message */
   event: (MsgArrival, CksumErr, TimeOut) /* different interrupt events */

2. **MsgBitSend** = 0 /* initialize alternating bit */
3. FromHost(sbuffer) /* get the data message from host */
4. repeat
5.   async_send(r, sbuffer, MsgBitSend) /* time to wait for acknowledgement */
6.   wait(event) /* possibilities MsgArrival, CksumErr, TimeOut */
7.   if event = MsgArrival /* a valid message has arrived */
8.     async_recv(r.ack) /* receive the acknowledgement */
9.     FromHost(sbuffer) /* an acknowledgement has arrived intact */
10. inc(MsgBitSend) /* increment by 1 then mod 2 */
11. endif
12. until doomsday
```

Procedures:

```
13. **MsgBitReceive**: bit /* alternating bit */
15. rbuffer: message /* buffer for incoming data message */
16. event: (MsgArrival, CksumErr) /* different interrupt events */

17. **MsgBitReceive** = 0 /* initialize alternating bit */
18. repeat
19.   wait(event) /* possibilities MsgArrival, CksumErr */
20.   if event = MsgArrival /* a valid message has arrived */
21.     async_recv(s. rbuffer, IncomingBit) /* accept the message */
22.     if IncomingBit = MsgBitReceive
23.       ToHost(rbuffer) /* pass the data to the host */
24.     endif
25.     inc(MsgBitReceive) /* increment by 1 then mod 2 */
26.   endif
27.   async_send(s. acknowledgement)
28. endif
29. until doomsday
```

The `async_send` command transmits a message (data message and bit) over the communication channel, and the `async_recv` command accepts a message from the communication channel and assigns the data message to `rbuffer` and the bit to `IncomingBit`. Procedure
StartTimer() starts the timer and enables the Timeout Event. Procedure Wait() waits for an event to happen, and returns the event type when one occurs. The procedure FromHost() fetches a data message from the host, and the procedure ToHost() delivers a data message to the host.
Chapter 3

Monitoring Methods

3.1 Global State

A partial order is defined on a distributed system's events when the system executes. The notion of a system state is complicated by the lack of a total order among events. An additional complication is the difficulty of capturing a system state since local memories are physically separate from one another. Despite the difficulties of a distributed computation's states, monitoring a distributed program requires reasoning about constituent processes' execution as a single collective entity. Previous work [28, 4, 38, 37, 29, 33] has defined a global state for unified reasoning about the distributed processes. A global state is analogous to "gluing" together local states, one from each process, such that the local states can happen at the same "time". The "gluing" produces one possible state of the system.

Global states provide a means to monitor a distributed system's execution with global predicates. A global predicate for a distributed system is comprised of relationships among variables from different processes. Once a global state is constructed, a global predicate
is evaluated on this state. Constructing a global state and evaluating a predicate on that state helps in any rational scheme for debugging and monitoring the distributed program.

3.2 Runtime Methods

Despite a global state's usefulness, problems exist with distributed system monitoring based on global states. A major problem is the difficulty of capturing a global state during the distributed system's execution.

Runtime methods of capturing a global state has been addressed by many researchers. Several papers that stand out in the literature are briefly described. Chandy and Lamport [4] were the first to define a global state as a global snapshot that could have occurred if all processes took a snapshot of their local states simultaneously. Their global snapshot algorithm assumes FIFO asynchronous communication and each process has at least one incoming and outgoing unidirectional communication channel. Process $P_i$ communicates directly with $P_j$ if a channel exists from $P_i$ to $P_j$, otherwise $P_i$ communicates indirectly with $P_j$ through intermediate processes and channels.

The snapshot algorithm consists of two phases. In the first phase, each process takes a snapshot of its state. In addition to the recorded local state information, the messages in-transit when the local snapshots are taken will be included in the global snapshot. The in-transit messages are flushed through the channels before the local snapshots are assembled into a global snapshot. A process initiates a global snapshot by (1) saving its local state, (2) sending a snapshot token message on each of its outgoing channels, and (3) beginning the
recording of messages on each incoming channel. The token informs the receiving process that a snapshot is being taken, and it flushes the messages in-transit so they are included in exactly one process’s local state. When a process receives a token, it performs the same three steps as the initiating process.

A process continues to record incoming messages for a channel until the process receives a snapshot token on the channel. Once a process has received a token on each channel, the process’s local state is complete for the global snapshot.

In the second phase, each process disseminates its local state information to form a global snapshot. Each process must send its state information to each of its neighbors, and when a process receives other processes’ states, it must relay this information to its neighbors. This type of dissemination ensures that the process requesting the snapshot eventually receives the global state.

Every process receives the global snapshot with Chandy and Lamport’s algorithm. Kearns and Spezialetti [38] improve the efficiency of the global snapshot algorithm by reducing the message-passing load for disseminating the global state. Only the process or processes that initiate the global snapshot receive it. The process(es) that initiate the snapshot by passing snapshot tokens include their process identification with the tokens. The tokens continue with their original purpose of informing other processes to record their local states. Once a process has completed recording its local state, the local state is only sent to the process that prompted this process to take a snapshot. Once a non-initiating process has sent its local state to the initiating process, it has completed the global snapshot since it no longer has the responsibility of sending neighboring processes’ state information.
Lai and Yang [18] extend the original global snapshot algorithm by removing the FIFO restriction. One status bit is associated with each process and is piggybacked on all messages. Each process’s bit is initially 0, and a process sets the bit to 1 when it initiates a snapshot. When a process receives a 1 status bit, its status bit is set to 1, and it takes a snapshot. Since the channels are non-FIFO, messages sent before the snapshot can still be in-transit after the snapshot is taken. These messages must be incorporated into the global snapshot. Each process keeps a record of all messages it has received and sent for calculating the in-transit messages.

Mattern [28] develops an algorithm similar to Lai and Yang’s for non-FIFO channels, but it does not require the processes to record messages. The algorithm ensures that the result of a process initializing a global snapshot is a consistent cut. A consistent cut is a set of events that are not causally related (concurrent), and each process has exactly one event in the cut. If an event \( e_i \) happens before \( P_i \)’s cut event, and \( e_j \) happens before \( e_i \), then \( e_j \) must happen before \( P_j \)’s cut event for the cut to be consistent. This condition disallows messages sent after the cut to be received before the cut. The only messages in-transit after the cut are messages with a status bit of 0 being sent to processes with a status bit of 1. The global snapshot comprises the local states resulting from the cut events and the in-transit messages.

The global snapshot algorithms described share a common problem, they add causal dependencies to a distributed system’s computation. To expose this problem, consider Chandy and Lamport’s snapshot algorithm. The recording of \( P_i \)’s local state and propagating the
CHAPTER 3. MONITORING METHODS

Figure 3.1: Local Snapshot phase of Global Snapshot Algorithm

snapshot token are events added to the distributed computation by the local snapshot phase of the algorithm. Figure 3.1 is a time-space diagram of a three processor system. The asynchronous messages of the computation (without the snapshot algorithm) are denoted with solid lines. The dashed lines represent snapshot token messages. The notation snapshot\(_i\) indicates the local snapshot of \(P_i\). Figure 3.1 shows both the local snapshots being taken and the propagation of the token, given that \(P_0\) initiated a global snapshot after \(e^2_0\). Assume no messages are in transit when the local snapshots are taken and the only communication channels are \(P_0\)'s outgoing channel to \(P_1\), \(P_1\)'s outgoing channel to \(P_2\), and \(P_2\)'s outgoing channel to \(P_0\). The global state obtained by this global snapshot is denoted by \(\text{global\_state}\), which is \(\bigcup_{i=0...2} \text{snapshot}_i\).

The token messages add causality to the computation. For the events \(e^1_0, e^2_0, e^3_0\) of \(P_0\), events \(e^5_1, e^6_1, e^7_1, e^8_1\) of \(P_1\), and events \(e^9_2, e^{10}_2, e^{11}_2\) of \(P_2\), there exist no causal relationship between \(e^m_i\) and \(e^j_i\) for \(i \neq j\), according to the distributed computation. For example, \(e^2_0\) and
$e_1^8$ are concurrent in the underlying computation. The token messages add (false) causality to these events as defined by the happens before relationship. Event $e_0^2$ happens before $e_1^8$ according to the causal relationship added by the token transmission from $P_0$ to $P_1$. The concurrent execution of $e_0^2$ and $e_1^8$ is inconsistent with the causal order defined by the token messages. Events $e_0^1$ and $e_0^3$ are causally related to $e_1^7$, $e_1^8$, and $e_2^{11}$. $e_1^5$ and $e_1^6$ are causally related to $e_0^1$, $e_0^4$, and $e_2^{11}$. and $e_2^3$ and $e_2^{10}$ are causally related to $e_0^3$ and $e_0^4$ due to the three token messages. For example, $e_0^2 \rightarrow e_1^7$ and $e_0^2 \rightarrow e_2^{11}$.

Adding causality to concurrent events invalidates legitimate global states of the underlying computation. For example, the cut consisting of events $e_0^1$, $e_1^7$, and $e_2^{11}$ is consistent in the underlying computation, but is an inconsistent cut due to the causality added by the token messages. Since the cut of $e_0^1$, $e_1^7$, and $e_2^{11}$ is not consistent, the global state consisting of the local states after the execution of $e_0^1$, $e_1^7$, and $e_2^{11}$ is not a valid global state. The global state defined by $e_0^1$, $e_1^7$, and $e_2^{11}$ is valid in the underlying computation.

Global snapshot algorithms require that obtaining a global state should not disrupt the computation of the distributed system, but these algorithms do interfere by imposing order on concurrent events. Distributed system monitors should be based on the uncorrupt computation of the system and should not allow a method that invalidates legitimate global states.

An additional problem with global snapshots is their usefulness. Global snapshots are only adequate for detecting stable properties. Once a stable property occurs, it persists until the system is terminated. Examples include deadlock and termination. Predicates expressing stable properties are called global stable predicates. By taking global snapshots...
periodically, a stable property can be detected by a predicate evaluated on the sequence of snapshots.

Distributed monitoring and debugging properties are, in general, not stable. Predicates for detecting unstable properties are called unstable predicates. Repeated snapshots are inadequate for evaluating an unstable predicate, as the property expressed by the predicate may have occurred between snapshots, and gone undetected.

Consider the distributed program SETPART. A reasonable and informative global predicate to evaluate after each exchange of maximum and minimum datum values is $S \cap T = \emptyset$. If this predicate evaluate to true, SETPART is correctly updating the sets after an exchange. But many global states are possible after an exchange. A simple execution of SETPART is shown in figure 3.2. Each dashed line represents a possible global state after the first
exchange. Figure 3.2 represents a valid execution of SETPART, but the evaluation of the global predicate may be either true or false. The predicate's evaluation does not provide insight into the correctness of the execution. If the global states are restricted by P₀ initiating the global snapshot after if receives x and adds x to S, two global states are possible: 

\[ S = \{1, 3\}, \quad T = \{1, 2, 5\} \quad \text{and} \quad S = \{1, 3\}, \quad T = \{2, 5\} \]

One resulting in a false evaluation of the predicate, and the other resulting in a true evaluation. Although SETPART's communication has a simple repeating pattern, it exemplifies the deficiencies of monitoring unstable properties with existing runtime methods.

Cooper and Marzullo [5] propose an algorithm. Currently, for evaluating an unstable predicate while the system is executing. A process sends a monitor process, \( P_{mon} \), its local state if the local state might affect the outcome of a known global predicate \( \Phi \). \( P_{mon} \) maintains the last received state of each process, and evaluates \( \Phi \) each time it receives a process's state. If \( \Phi \) evaluates to true, \( P_{mon} \) has detected an undesirable global state.

When a process enters a state that might falsify the evaluation of \( \Phi \), it freezes and sends a block message to \( P_{mon} \) before informing \( P_{mon} \) of its new state. The process remains blocked until \( P_{mon} \) has received all in-transit messages from the other processes. This flushing of messages allows \( P_{mon} \) to obtain in-transit states that might detect the predicate. Once the messages have been flushed, the blocked process sends \( P_{mon} \) its state and continues execution.

Although Currently's objective is detecting unstable predicates, it is equivalent to taking snapshots periodically, and it can miss a state on which \( \Phi \) evaluates to true. Currently incurs the same problem as the previously described algorithms, legitimate global states are

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
invalidated by imposing causal relationships on concurrent events. When processes send state information to \( P_{\text{mon}} \) and receive acknowledgements from \( P_{\text{mon}} \), order is imposed on concurrent events.

### 3.3 Postmortem Methods

Instead of capturing a global state while the system is executing, the postmortem algorithms \textit{Definitely} and \textit{Possibly} by Cooper and Marzullo [5] construct a lattice of all consistent global states based on trace data gathered during execution. \textit{Possibly} \( \Phi \) evaluates to true if there exists a global state which causes \( \Phi \) to be true. \textit{Definitely} \( \Phi \) evaluates to true if for all total orders there exists at least one global state in each total order which causes \( \Phi \) to be true. \textit{Possibly} and \textit{Definitely} provide a meaningful evaluation of unstable predicates since all global states are considered.

\[ \begin{align*}
\text{\textbf{Figure 3.3: Two asynchronously communicating processes}}
\end{align*} \]

\[ \begin{align*}
\text{\textbf{Figure 3.4: Lattice of global states}}
\end{align*} \]
While the distributed system is running, each process informs $P_{mon}$ of each local state it enters. $P_{mon}$ maintains a FIFO list of these states for each process. Once the execution has completed, $P_{mon}$ assembles the local states to construct a lattice of all consistent global states. Figure 3.4 shows the lattice constructed for the 2 processor distributed execution of figure 3.3. Point $S_{i,j}$ of the lattice is the global state where $i$ events have occurred on $P_1$, and $j$ events have occurred on $P_2$. The level of $S_{i,j}$ is $i+j$. A possible total ordering of states is a path starting at the level 1 global state, and each subsequent global state has a level increase of one. Possibly is true if at least one point in the lattice satisfies $\Phi$. Definitely is true at least one point in every total ordering satisfies $\Phi$.

Definitely and Possibly provide a meaningful predicate evaluation methodology by considering all global states. The outcome of evaluating $\Phi$ provides unambiguous information about the system’s behavior. Although they provide meaningful results, the inability to monitor the system at runtime is a significant weakness of both algorithms. By waiting for the system to complete execution, on-line corrective actions such as recovery or abortion can not be made for invalid execution behavior. Real-time feedback is crucial for life- or mission-critical control applications.

We have developed a runtime method for monitoring a distributed system that is meaningful for both stable and unstable properties. Predicates are evaluated with all the processes’ state information that may affect the evaluation. Any invalid system state, indicated by evaluation of the predicate, is detected. Evaluation is only with system states that can occur in the distributed computation, and legitimate global states are not invalidated. The following chapter describes our methodology, both in terms of design and implementation.
Chapter 4

Causal Distributed Assert Statement

Some sequential programming languages [39, 40] facilitate predicate evaluation with assert statements. An assert statement [30] (or library function, depending on its implementation) generally has the form

\[
\text{assert}(P)
\]

where \( P \) is a predicate defined on the state of the program. The semantics of this assert statement are that \( P \) is evaluated, without side-effects, on the program state at the point at which the \text{assert} () is executed. If \( P \) is true then the program continues its execution. If \( P \) is false, however, the program is aborted, and a diagnostic message is produced.

We have extrapolated the semantics of the assert statement for sequential programs into the distributed context. A distributed assert statement is a global predicate that is anchored at a control point of one process, and that is evaluated when the process executes
the assert. A distributed assert statement monitors a distributed system’s execution, but only a subset of the system states of the execution are relevant for evaluating the assert. Two possibilities exist for which portion of the execution the distributed assert monitors. One possibility is the distributed assert statement monitors the global states that are defined by consistent cuts including the assert statement. This interpretation is in accord with the global predicate evaluation methods described in chapter 3. If the distributed assert monitors concurrent execution, then any consistent cut of the system that includes the assert event defines a valid global state for predicate evaluation. A simplistic three processor system is shown in figure 4.1. The broken lines represent all possible consistent cuts, and the × represents an assert statement.

The only previous work that resembles this interpretation of the distributed assert statement is Cooper and Marzullo's Currently[5]. Currently evaluates the global predicate Φ while the system is executing and is claimed to be appropriate for unstable predicates. But Currently is incomplete: global states can be missed that cause a true evaluation of Φ [33]. Currently is also intrusive of the system’s execution since it introduces extra synchronization into the monitored computation, and it can cause a significant degradation in system performance. Every modification of a variable in Φ can be considered a possible invalidation of Φ, causing the network to be congested with block and acknowledgment messages and causing the process about to execute the modification to freeze until all in-transit messages to P_mon are received.

Another interpretation of the distributed assert statement is that it monitors the execution that has the most recent causal impact on the assert statement. We have developed
a methodology for evaluating a distributed assert statement in accordance with this interpretation. Our methodology does not have the problems associated with global state reasoning. The state of the system necessary for evaluating the predicate is well-defined, and the evaluation result relays unambiguous information about the state of the system. Our distributed assert statement is characterized by two properties:

A1 The asserted predicate is evaluated during execution of the program. We do not generate and analyze traces post mortem.

A2 No additional synchronization or message passing is added to the original distributed application in support of the distributed assert statement. We do increase the size of some application messages.
4.1 Model and Notation

Recall that a distributed program consists of a fixed number of processes \( \Pi = \{P_0, \ldots, P_{N-1}\} \), and the happened before relationship, \( \rightarrow \), is a partial order on the program’s events. For event \( e \) in \( P_i \), \( LCP(e, j) \) where \( j \neq i \), denotes event \( e \)'s latest causally preceding event in \( P_j \).

We define \( LCP(e, j) = f \) if and only if \( f \) is an event in \( P_j \), such that \( f \) happens before \( e \) and there does not exist event \( f' \) in \( P_j \) such that \( f \) happens before \( f' \) and \( f' \) happens before \( e \).

**Definition 4.1** For some event \( e \in P_i \), the latest causally preceding event in \( P_j \) where \( j \neq i \), denoted \( LCP(e, j) \), is event \( f \) if and only if

1. \( f \in P_j \)
2. \( f \rightarrow e \)
3. \( \exists f' \in P_j : f \rightarrow f' \rightarrow e \)

One of possibly many partial orders is defined when a distributed system executes. This is due to branches in control of execution and to the fact that communication delays and process speeds are unpredictable. Hence sends and receives will “match up” unpredictably in general. Consider the source code of a three process distributed system shown in figure 4.2. One of possibly two partial orders is defined when this program executes. The two possible partial orders, \( PO_1 \) and \( PO_2 \), are shown in figure 4.3. Set \( \mathcal{P} \) is the set of possible partial orders of a distributed system’s execution. For the distributed system shown in
$P_0::$

\begin{verbatim}
begin
  x = 1
  async_send(1, x)
  x = 2
  async_send(1, x)
end
\end{verbatim}

$P_1::$

\begin{verbatim}
begin
  if
    async_recv(0, x)
  else
    async_recv(0, x)
  endif
  async_recv(2, y)
  async_recv(0, x)
end
\end{verbatim}

$P_2::$

\begin{verbatim}
begin
  y = 3
  async_send(1, y)
end
\end{verbatim}

Figure 4.2: 3 process distributed system

Figure 4.2. $\mathcal{P} = \{PO_0, PO_1\}$. For a given execution of the distributed system, one partial order, $\alpha \in \mathcal{P}$, is produced.

For a partial order, $\alpha \in \mathcal{P}$, at most one LCP event exists in each process for any event $e$. Each partial order may identify a different $LCP(e, j)$. The maximum unique $LCP$ events of $P_j$ for event $e$ is bounded by the number of partial orders, i.e., the size of set $\mathcal{P}$.

**Lemma 4.1** For a partial order $\alpha \in \mathcal{P}$ of a distributed system and an event $e$ of $P_i$, at most one $LCP(e, j)$ exists for $j \neq i$.

**Proof by contradiction.** Assume two $LCP(e, j)$ events, $e'$ and $e''$, exist for the one partial order $\alpha$. According to the definition of $LCP$ events (definition 4.1),

1. $e' \rightarrow e$, and there does not exist another event $f$ such that $e' \rightarrow f \rightarrow e$

2. $e'' \rightarrow e$. and there does not exist another event $f$ such that $e'' \rightarrow f \rightarrow e$
CHAPTER 4. CAUSAL DISTRIBUTED ASSERT STATEMENT

From 1. and 2. \( e' \not\Rightarrow e'' \) and \( e'' \not\Rightarrow e' \). therefore \( e' \parallel e'' \). The concurrency of \( e' \) and \( e'' \) is a contradiction since both are events of \( P_j \) and the events of one process are totally ordered.

Consider event \( e \) in process \( P_i \). A causal cut through \( e \) is the set of events consisting of \( e \) and the LCP event of \( e \) of each process for a partial order \( \alpha \).

**Definition 4.2** A causal cut through event \( e \), denoted \( CC(e) \), is defined as

\[
CC(e) = \{e\} \cup \left( \bigcup_{0 \leq j < N} \{LCP(e, j)\} \right). 
\]

Intuitively, \( CC(e) \) is the "latest" set of events of \( \Pi \) which can have a causal impact upon \( e \).

In figure 4.4, the causal cut through \( P_0, P_1, \) and \( P_2 \) for event \( e \) is shown as a dashed line.

An event \( f \) is said to be before causal cut \( CC(e) \) if there exists event \( g \in CC(e) \) such that
CHAPTER 4. CAUSAL DISTRIBUTED ASSERT STATEMENT

$f \rightarrow g$: $f$ is after $CC(e)$ if there exists event $g \in CC(e)$ such that $g \rightarrow f$. Accordingly, we use $CC$ to define a notion of global state to be used in the evaluation of a distributed assert statement.

---

A causal cut does not necessarily include an LCP event from each process since each process may not have an event that occurs before an event $e$. For each $\alpha \in \mathcal{P}$, there is one causal cut for a given event. Also, the LCP events that comprise the causal cut for an event and one partial order may differ from the LCP events that comprise the causal cut for the same event and a different partial order.

**Theorem 4.1** For a partial order $\alpha \in \mathcal{P}$ of a distributed system and an event $e$ of $P_i$, at most one $CC(e)$ exists.

**Proof.** This follows directly from Lemma 4.1 and Definition 4.2. Since each process has at most one $LCP(e, j)$ for each $\alpha \in \mathcal{P}$ (lemma 4.1) and $CC(e)$ is comprised of the $LCP(e, j)$
from each process (definition 4.2), at most one $CC(e)$ can exist.

For event $e$ in process $P_i$, let $pre(e)$ denote the local state of $P_i$ in which the execution of $e$ is begun. Execution of $e$ effectively terminates state $pre(e)$. If $e$ is the execution of a causal distributed assert statement in $P_i$, then the causal global state, anchored on $e$, is simply

$$CGState(e) = \{pre(f) : f \in CC(e)\}.$$ 

$CGState$ is the set of process states which immediately precede the causal cut through $e$. the execution of the assert statement. $CGState$ thus incorporates the state of the system as a whole as it may have causal impact upon $P_i$ at the point the assert statement is executed. Events which are after the causal cut through $e$ cannot affect the execution of $e$. All events which happen before the causal cut will have their effect on $e$ through transitivity.

![Diagram of causal global state for an assert](image)

**Figure 4.5:** Causal Global State for an Assert

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
Figure 4.5 shows a causal distributed assert statement being evaluated in process $P_1$. The horizontal lines across the process time lines represents events, and the dashed line represents $CC(\text{assert}(P))$. The individual process states compromising the causal global state anchored on the assert is denoted by x’s on the process time lines. Partial orders $PO_0$ and $PO_1$ each have a corresponding causal cut and causal global state. Although in this example the causal cut and causal global state are identical, in other distributed systems they can be different. The causal global state is $P_0.x = 2$ and $P_2.y = 3$ for both partial orders.

### 4.2 Implementation

Our implementation of the causal distributed assert statement ensures that when an assert is executed, the relevant components of the causal global state are immediately available at the process executing the assert (Property A1). To that end, process $P_i$ maintains its current view of the $CGState$ in the causal global state buffer, $CGBuffer_i$. Processes maintain their causal global state buffers independently. Buffer maintenance requires no message-passing or synchronization beyond that required by the underlying application (Property A2). Each causal state buffer consists of tuples of the following form

$$(\text{process id}, \text{variable name}, \text{variable value}, \text{vector timestamp})$$

The meaning and use of vector timestamp is discussed below. A process maintains its causal state buffer to contain only the latest (causally speaking) state information for each process.
When an assert statement is executed in $P_i$, say at event $e$, $CGSBuffer_i$ will contain all components of $CGState(e)$.

A process receives state information from each process in the system by having the processes piggyback state information on application messages. When a process sends an application message, it piggybacks its $CGSBuffer$ on the message. Process $P_j$ acquires state information from $P_i$ when $P_i$ directly communicates with $P_j$ or when $P_i$ indirectly communicates with $P_j$. Process $P_i$ directly communicates with $P_j$ by sending a message to $P_j$. Process $P_i$ indirectly communicates with $P_j$ by sending a message to another process $P_k$ and $P_k$ either directly or indirectly communicates with $P_j$. If $P_i$ does not directly or indirectly communicate with $P_j$, then $P_i$ does not contribute to $P_j$'s causal global state. In this case, $LCP(e, i)$ does not exist.

Consider the communication pattern shown in figure 4.6. $P_2$ receives state information for $P_0$ from two different sources: the message $P_0$ sends to $P_2$, and the message $P_1$ sends to $P_2$. When $P_1$ and $P_2$ communicate, $P_2$ requires a mechanism for determining the causally latest value of $x$. $P_2$ has one value of $x$ in $CGSBuffer_2$ from its direct communication with $P_0$, and a new arriving value of $x$ is piggybacked on $P_1$'s message to $P_2$. In fact, the newly arriving value of $x$ is stale and should not overwrite the tuple for $x$ in $CGSBuffer_2$. Vector time [29] is the mechanism we adopt for determining the latest causal values associated with variables.

Timestamping a set of events with vector time has been shown to be isomorphic to the causal partial order on those events [33]. Each $P_i$ maintains a vector $V_i$ of $N$ integers, $(V_i[0], \ldots, V_i[N-1])$, where $V_i[i]$ is the counter of the number of events which have occurred.
on $P_i$. $V_i[i]$ is incremented before each event in $P_i$. $V_i(e)$ is the vector time of event $e$ of process $P_i$. The vector time associated with event $e$ is also associated with the state resulting from $e$. The rules for maintaining asynchronous vector time are:

1. Initially, for each $P_i$, $V_i[j]=0$ for $0 \leq j < N$

2. $V_i[i]=V_i[i]+1$ when an event occurs on $P_i$.

3. Suppose $P_i$ sends a message to $P_j$, and $e_i$ and $e_j$ are the corresponding send and receive events, respectively. If $V_i=(V_i[0],\ldots,V_i[N-1])$ corresponds to $e_i$ and $V_j=(V_j[0],\ldots,V_j[N-1])$ corresponds to $e_j$, then as a result of $P_i$ and $P_j$ communicating, $P_j$ updates its vector clock to

$$V_j(e_j) = \text{MAX}((V_i[0],\ldots,V_i[i]+1,\ldots,V_i[N-1]),(V_j[0],\ldots,V_j[j]+1,\ldots,V_j[N-1])).$$

where MAX designates component-by-component maximum.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig4_6.png}
\caption{Latest State}
\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig4_7.png}
\caption{Vector Time}
\end{figure}
Vector time can be used to indicate the relative "causal timeliness" of state information. Suppose \( P_j \) propagates a state datum stamped with a vector time to \( P_k \). If the datum is a variable of \( P_j \), it will be timestamped with the vector time of \( P_j \) just before the communication with \( P_k \). If, however, the datum is not local to \( P_j \) or \( P_k \), then it must reside in \( CGSBuffer_j \) (it is being propagated in order to handle the indirect communication), and the vector time of the component's tuple in \( CGSBuffer_j \) will be used. Upon receipt of the vector timestamped datum (assume the datum resides at \( P_i \)), the \( i \)th component of its timestamp is compared with the \( i \)th component of the vector timestamp of the tuple in \( CGSBuffer_k \) associated with the appropriate variable of \( P_i \). If the \( i \)th vector component of the tuple in \( CGSBuffer_k \) is greater than or equal to the \( i \)th component of the timestamp on the incoming datum, then the copy in \( CGSBuffer_k \) is the valid latest causal value of the variable, and the tuple is not updated. Otherwise, the incoming datum is causally later than the value of the variable stored in \( CGSBuffer_k \), and the tuple must be overwritten with the incoming datum.

Figure 4.7 is derived from figure 4.6 by adding vector time. Note that \( P_2 \) receives two copies of the datum for \( P_0 \)'s variable \( x \). It receives \( x \) with value 1 and vector timestamp \([3.0, 0]\) when \( P_0 \) sends a message to \( P_2 \). The tuple \((P_0, x, 1, [3.0, 0])\) is inserted into \( CGSBuffer_2 \). When \( P_0 \) sent a message to \( P_1 \), the tuple \((P_0, x, 0, [1.0, 0])\) was inserted into \( CGSBuffer_1 \). When \( P_1 \) sends a message to \( P_2 \), \( P_1 \) forwards a datum for \( x \) with value 0 and vector timestamp \([1.0, 0]\) to \( P_2 \) to account for the indirect communication between \( P_0 \) and \( P_2 \). However, when \( P_2 \) receives the second datum for \( x \), the first component of the datum's timestamp, 1, is compared to the first component of the vector timestamp for \( P_0 \)'s \( x \) in...
CSBuffer. 3. Process $P_2$ then knows to discard the second datum.

The causal state propagation is implemented by the protocol shown in figure 4.8 on each communication. This protocol is not intended as a final implementation but as a foundation for a more efficient result.

**Protocol: Causal State Propagation**

$P_i$ sends to $P_j$:

$V_i[i] = V_i[i] + 1$

**send** (msg, $V_i$,$\text{CGSBuffer}_i$) to $P_j$

$P_j$ receives from $P_i$:

$V_j[j] = V_j[j] + 1$

**receive** (msgbuffer, $V_i$, Tmp_Buffer) from $P_i$

Update($\text{CGSBuffer}_j$, Tmp_Buffer)

$V_j = \text{MAX}(V_i,V_j)$

**consume**(msgbuffer)

**Figure 4.8:** Propagation Protocol

To simplify the presentation, the above pseudo-code assumes that each process keeps its local state in its causal state buffer along with remote state components it has acquired via message passing. The Update procedure in figure 4.9 is invoked to alter the local causal state buffer based on this communication.

**Procedure Update(B1,B2)**

Updates local state buffer $B_1$ based on contents of remote buffer $B_2$.

Recall that buffer tuples contain fields (Pid. var. value. V)

for all tuples $T$ in $B_2$ do

if ($T$.Pid.$T$.var.$\ast$.*) not in $B_1$

insert $T$ in $B_1$

else /* Let $T'$ be the tuple in $B_1$ matching $T$. */

if $T'.V[T'.\text{Pid}] < T.V[T.\text{Pid}]$

replace $T'$ with $T$

endfor

**Figure 4.9:** Update Causal State Buffer
The asynchronous communicants piggyback state information on all messages to track the causal global state. Although this does guarantee that the causal global state is immediately available for the process evaluating the assert, we piggyback all state information on all messages. Optimizations of this naive approach are addressed in chapters 5, 6 and 7.
Chapter 5

Optimization

5.1 Timing Results

Our evaluation of an assert statement alters the distributed system by piggybacking data on existing messages, resulting in increased message sizes. Intuitively, one way message transmission time is linear in size of the message. To verify linear transmission time increases, we have conducted an experiment with datagram communication on real systems.

Two processes, $P_{sender}$ and $P_{receiver}$, communicate with each other through UDP/IP datagrams. $P_{sender}$'s and $P_{receiver}$'s only function is communicating with each other. This provides an adequate environment to measure the full impact of increased message length on execution time. $P_{sender}$ sends to $P_{receiver}$ 1,000 datagrams, and for each datagram sent, $P_{sender}$ waits for an acknowledgment from $P_{receiver}$ before sending the next datagram. One thousand samples of $P_{sender}$'s execution time are gathered to obtain a sufficient number of samples to determined $P_{sender}$'s average execution time with 95% confidence. For the first 1,000 samples, the datagram size is 50 bytes. The datagram size is incremented by 50 bytes,
and samples are gathered for each datagram size. This experiment is completed after the samples are gathered for a 3500 byte datagram. The experiment is conducted between two Sun workstations running SOLARIS 1.1. The average execution times and associated 95% confidence intervals are plotted in figure 5.1. The same experiment is conducted on two additional machine platforms and similar results are obtained. For one platform, the sender is an IBM RS6000 workstation running AIX 3.23, and the receiver is a Sun workstation. For the other platform, the sender is a DECstation 5000 workstation running Ultrix 4.2A, and the receiver is a Sun workstation.

Figure 5.1: Datagram experiment

In all three datagram experiments, the execution times are roughly linear as message size increases. Common to all three experiments is a fluctuation in execution time when the message size is approximately 1500 and 3000. The significance of these numbers lies in the maximum transmission unit (MTU) for the Sun which is 1500 bytes, and datagram fragmentation into packets occurs for every MTU. The Internet protocol (IP) layer, or network
layer, is responsible for fragmentation into packets and reconstruction of the datagram. The overhead of fragmentation occurs when the message size reaches an MTU multiple. The important conclusion gained from the datagram experiment for assert statement evaluation is that increasing the message size does increase the execution time of a distributed system, but the increase is linear in the size of the piggybacked data.

5.2 Piggybacking messages

The naive implementation described for a causal distributed assert statement constructs a causal state buffer consisting of each process’s causally latest state information. Each process piggybacks its entire causal state buffer on the application messages. This does ensure that all data is available for assert statement evaluation, but one expects that a majority of the data is not necessary for the evaluation. The amount of state information gathered in the causal state buffers and piggybacked onto messages can be reduced by preprocessing with regard to the assert statement.

If the messages that are not necessary for delivering the CGState can be identified, the number of messages marked for piggybacking can be reduced. The LCP events are the means by which we reduce the number of messages piggybacking state information. The first step in achieving our reduction is showing that LCP events are communication events.

**Lemma 5.1** For event e of Pi, each LCP(e, j), j \( \neq i \) is a communication event.

**Proof.** According to the happens before relation and the definition of LCP events (definition 4.1), if there exists an LCP(e, j), then there must exist a communication event f in
$P_j$ such that $f \rightarrow e$, and there does not exist another communication event $f'$ in $P_j$ such that $f \rightarrow f' \rightarrow e$. Events in $P_j$ either occur before or after $f$. Consider an event $g \neq f$ in $P_j$. There are two cases:

1. Assume $g \rightarrow f$. Since $g \rightarrow f \rightarrow e$ and an event that occurs before $f$ is not $LCP(e, j)$, it follows that $g$ is not $LCP(e, j)$.

2. Assume $f \rightarrow g$. Since there does not exist a communication event after $f$ that happens before $e$, we know $g \not\rightarrow e$. Therefore $g$ is not the $LCP(e, j)$.

We can conclude from 1. and 2. that $LCP(e, j)$ is the communication event $f$.

For asynchronous message passing, each $LCP$ event is a send. We will be concentrating on results for asynchronous message passing, but our results can easily be extended to (the less practically significant) synchronous message passing.

**Lemma 5.2** For event $e$ of $P_i$, each $LCP(e, j)$, $j \neq i$, is a send event.

**Proof.** We know from lemma 5.1 that each $LCP$ event is either a send or receive event. Assume that the event $e_{j \neq i} = LCP(e, j)$ is a receive event. For $e_j$ to be the $LCP(e, j)$, $e_j \rightarrow e$ and there does not exist another event $e'_j$ such that $e_j \rightarrow e'_j \rightarrow e$ (definition 4.1).

For an event of $P_j$ to happen before an event of $P_i$ process, there must exist a causal chain of communication events from $P_j$ to $P_i$ where the causal chain begins with $P_j$ sending a message and ends with $P_i$ receiving a message (definition of $\rightarrow$). For $e_j$ to happen before $e$ there must exist a send event $e''_j$ in $P_j$ that happens after $e_j$ and that happens before the
event $e$. Since $e_j \rightarrow e_j'' \rightarrow e$ and $e_j''$ is a send event, the receive event $e_j$ can not be an $LCP$ event.

\[\hfill\]

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure.png}
\caption{LCP and $LCP'$ events of the Assert Event}
\end{figure}

Corresponding to each $LCP$ send event is a receive event, denoted $LCP'$. A causal cut for event $e$ consists of $LCP$ send events. The $LCP$ and $LCP'$ events of the distributed program shown in figure 4.2 are shown in figure 5.2. The wider communication line indicates the message of the $LCP$ and $LCP'$ events. The $LCP$ and $LCP'$ events of a partial order comprise the communication events that are sufficient for delivering the $CGState$ data to the process evaluating the assert. Before proving this property, the following definitions are necessary:

\textbf{Definition 5.1} A communication path of length $t + 1$ from $e_j^0$ to $e_i^t$, where $t$ is odd and $j \neq i$, is a series of communication events $e_j^0, \ldots, e_i^t$ such that

1. $e_j^0$ is the only communication event of $P_j$ in the path.
CHAPTER 5. OPTIMIZATION

2. $e_i^1$ is the only communication event of $P_i$ in the path.

3. $e_k^r \rightarrow e_i^{r+1}$, where $k \neq i$ or $k = i$, and there does not exist an event $e'$ that is an event of the path such that $e_k^r \rightarrow e' \rightarrow e_i^{r+1}$.

4. for $e_k^r$ and $e_i^{r+1}$, where $k \neq i$ and $r$ is even, $e_k^r$ and $e_i^{r+1}$ are a send/receive pair ($e_k^r$ being the send and $e_i^{r+1}$ being the receive), and

5. for $e_k^r, e_i^{r+1}$, where $k \neq i$, the next event of the path (if it exists) must occur on $P_i$, denoted $e_i^{r+2}$, and the the event following $e_i^{r+2}$ is not an event of $P_i$.

If $e_j^0, e_k^1, e_j^2, e_i^1, e_i^2$ is a valid communication path of length 6, $e_j^0$ is a send to $P_k$; $e_k^1$ is the receive corresponding to $e_j^0$, $e_k^2$ is a send to $P_i$, $e_i^3$ the receive corresponding to $e_k^2$, and $e_i^1$ is a send to $P_i$, and $e_i^5$ is the receive corresponding to $e_i^4$.

**Definition 5.2** A non-repetitive communication path is a communication path such that when two communication events of $P_k$ occur in the path $..., e_k^r, e_k^{r+1}, ...,$, no other events of $P_k$ can occur in the path.

A non-repetitive communication path differs from a communication path in that

- if $P_k$ has events in the path, $k \neq j$, and $k \neq i$, then exactly one send and one receive of $P_k$ occurs in the path.

- $P_j$ has exactly one event in path, the send event $e_j^0$, and

- $P_i$ has exactly one event in the path, the receive event $e_i^1$.

A non-repetitive communication path is a special case of a communication path.
Lemma 5.3 If a communication path exists from $e^0_j$ to $e^i_j$, then at least one non-repetitive communication path exists from $P_j$ to $P_i$ consisting of a subset of the events of the communication path.

Proof by contradiction. Assume a communication path exists from $e^0_j$ to $e^i_j$ but a non-repetitive communication path does not exist from $P_j$ to $P_i$ consisting of a subset of the events of the communication path.

Consider the communication path from $e^0_j$ to $e^i_i$.

Case 1.

The communication path from $e^0_j$ to $e^i_i$ is not a non-repetitive communication path due to there existing at least two send commands and two receive commands of the same process $P_k$, $k \neq j, k \neq i$, in the path. Let $p = e^0_j, \ldots, e^{r-1}_k, e^r_k, \ldots, e^{r+l}_k, e^{r+l+1}_k, \ldots, e^i_i$ represent such a path where $P_k$ is the only process that has multiple send and receives in the communication path. The events $e^{r-1}_k$ and $e^{r+l}_k$ are receive events of $P_k$, and the events $e^{r+l}_k$ and $e^{r+l+1}_k$ are the send events of $P_k$. We know from the definition of a communication path that $e^{r-1}_k \rightarrow e^r_k \rightarrow e^{r+l}_k \rightarrow e^{r+l+1}_k$. We also know that $e^0_j, \ldots, e^{r-1}_k$ is a non-repetitive communication path and that $e^{r+l+1}_k, \ldots, e^i_i$ is a non-repetitive communication path, therefore $e^0_j, e^{r-1}_k, e^{r+l+1}_k, \ldots, e^i_i$ is a non-repetitive communication path.

Case 2.

The communication path from $e^0_j$ to $e^i_i$ is not a non-repetitive communication path due to there existing in addition to the send command $e^0_j$ at least one send and receive
of $P_j$ in the path. Let $p = e_j^0, \ldots, e_j^{r-1}, e_j^r, \ldots, e_j^t$ represent such path. The event $e_j^{r-1}$ is a receive event of $P_j$ and $e_j^r$ is a send event of $P_j$. We know from the definition of a communication path that $e_j^0 \rightarrow e_j^{r-1} \rightarrow e_j^r$. We can conclude that $e_j^r \ldots e_j^t$ is a non-repetitive communication path.

Case 3.

The communication path from $e_j^0$ to $e_j^t$ is not a non-repetitive communication path due to there existing in addition to the receive command $e_j^t$ at least one send and receive of $P_i$ in the path. Let $p = e_j^0, \ldots, e_i^{r-1}, e_i^r, \ldots, e_i^t$ represent such path. The event $e_i^{r-1}$ is a receive event of $P_i$ and $e_i^r$ is a send event of $P_i$. We know from the definition of a communication path that $e_i^{r-1} \rightarrow e_i^r \rightarrow e_i^t$. We can conclude that $e_j^0 \ldots e_i^{r-1}$ is a non-repetitive communication path.

If a non-repetitive communication path exists from event $e_i$ to event $e_j$, then event $e_i$ happens before $e_j$. Also, if event $e_i$ happens before event $e_j$, then there exists a non-repetitive communication path from $P_i$ to $P_j$ where the first event of the path happens after $e_i$ and the last event of the path happens before $e_j$.

**Lemma 5.4** Event $e_j$ happens before $e_i$ if and only if there exists a non-repetitive communication path from a send of $P_j$ that happens after $e_j$ and a receive of $P_i$ that happens before $e_i$. 

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
CHAPTER 5. OPTIMIZATION

Proof

If $e_j \rightarrow e_i$, then there exist a non-repetitive communication path from a send of $P_j$ that happens after $e_j$ and a receive of $P_i$ that happens before $e_i$.

Assume $e_j \rightarrow e_i$ but there does not exist a non-repetitive communication path that starts with a send event of $P_j$ that happens after $e_j$ and ends with a receive event of $P_i$ that happens before $e_i$.

For $e_j \rightarrow e_i$, there must be communication path, $e_j^0 \ldots e_i^t$, such that $e_j \rightarrow e_j^0$ and $e_i^t \rightarrow e_i$ ($e_j$ can be $e_j^0$ and $e_i$ can be $e_i^t$). From lemma 5.3 we know that there must also exist at least one non-repetitive communication path from $P_j$ to $P_i$ that consist of a subset of the communication path $e_j^0 \ldots e_i^t$.

If there exists a non-repetitive communication path from a send of $P_j$ that happens after $e_j$ and a receive of $P_i$ that happens before $e_i$ then $e_j \rightarrow e_i$.

Proof. Let $e_j'$ be the send event that happens after $e_j$ and $e_i'$ be the receive event that happens before $e_i$. From definition 5.2, we know that $e_j' \rightarrow e_i'$ and therefore $e_j \rightarrow e_i$.

\[ \blacksquare \]

Theorem 5.1 For each $LCP(e_i, j)$ event of $CC(e_i)$, there exists a non-repetitive communication path from $LCP(e_i, j)$ to an $LCP'$ of $P_i$ such that each event of the path is either an $LCP$ event or an $LCP'$ event.
Proof.

Case 1 For each $LCP(e_i, j)$ event of $CC(e_i)$, there exists a non-repetitive communication path from $LCP(e_i, j)$ to a receive event $e_i'$ such that $e_i' \rightarrow e_i$.

Let $e_j = LCP(e_i, j)$. From lemma 5.2, we know $e_j$ is a send event. From definition 4.1 we know $e_j \rightarrow e_i$. From lemma 5.4, we know there exists a non-repetitive communication path from $e_j$ to some receive $e_i'$ such that $e_i' \rightarrow e_i$.

Case 2 The non-repetitive communication path that exists from $LCP(e_i, j)$ to receive event $e_i'$ consists of $LCP$ and $LCP'$ events.

Case 2.A The send events of the path are $LCP$ events.

In order for every non-repetitive communication path that exists from $LCP(e_i, j)$ to event $e_i'$ not to consist of $LCP$ send events, in each path there must exist at least one send event in $P_k$, $e_k$, that is not an $LCP$ event.

Since $e_k$ is a send event of a non-repetitive communication path from $e_j$ to $e_i'$, we know from definition 5.2 that $e_k \rightarrow e_i$. For $e_k$ to not be an $LCP$ event, there must exist another event, $e_k'$, of $P_k$ such that $e_k \rightarrow e_k' \rightarrow e_i'$; i.e., $e_k'$ is $LCP(e_i, k)$.

From this follows a contradiction. If $e_k'$ exists then there does exist a non-repetitive communication that includes $LCP(e_i, k) = e_k'$ according to 5.4. If $e_k'$ does not exist, then $e_k$ is the $LCP(e, k)$.

Case 2.B The receive events of the path are $LCP'$ events.

We know from case 2.A that the sends of a non-repetitive communication path
from $e_j$ to $e'_i$ are LCP events. And from definition 5.2, the receives of the path correspond to the sends, therefore the receives are LCP' events.

The following theorem is the basis for reducing the number of messages on which state information is piggybacked.

**Theorem 5.2** If the state data of the processes are piggybacked only on the messages of the LCPs and LCP's of the CC(e) of the current execution, the process executing the assert statement is delivered exactly the CGState prior to the assert statement's execution.

**Proof.** This follows directly from theorem 5.1. From theorem 5.1 we know there exists a non-repetitive communication path from each LCP event to an LCP' of $P_i$ that consists of LCP and LCP' events. If a process only piggybacks its local state information, and the state information it has received from other processes, on the message corresponding to its LCP event, the data will be received by $P_i$'s LCP' event(s).

Our first objective in reducing the amount of piggybacked data is to analyze the source code of the distributed processes to determine all possible partial orders and the LCP and LCP' events of each partial order. Chapters 6 and 7 explain our static analysis methods for achieving this objective.
Chapter 6

Static Analysis

6.1 Goals of Static Analysis

The causal state propagation protocol presented in chapter 4 satisfies the two properties of the distributed assert:

A1 The asserted predicate is evaluated during execution of the program. We do not generate and analyze traces post mortem.

A2 No additional synchronization or message passing is added to the original distributed application in support of the distributed assert statement. We do increase the size of some application messages.

This protocol can be improved by reducing the amount of data piggybacked. We know from the timing experiments in chapter 5 that these reductions will result in less interference with message transmission time. Hence, the “natural” time in the program can be preserved.

The objective of static analysis is to determine which send and receive events are the LCP
and $LCP'$ events of the assert. By piggybacking data only on these messages, the assert statement is evaluated with the $CGState$ and the amount of data piggybacked is reduced.

The first step in our static analysis is to examine the source code of each process and generate a flow graph. From the flow graphs, communication analysis matches send and receive events to generate a tree called a partial order graph ($POG$). We prove that the $POG$ represents all partial orders of the distributed system (property 6.12) and that each path of the $POG$ from root to a leaf node represents a unique partial order (property 6.13). After analyzing the source code and generating the $POG$, our technique detects the $LCP$ and $LCP'$ events for an assert statement. Properties 6.14 and 6.15 are our concluding properties of our analysis, and these properties establish that our technique for identifying $LCP$ and $LCP'$ events is valid.

By performing this analysis before execution, a reduction in the amount of piggybacked data is achieved by tagging the $LCP$ and $LCP'$ events as piggybacking events, and properties A1 and A2 are upheld. Before presenting algorithms for identifying the $LCP$ and $LCP'$ events, Taylor's static analysis technique is discussed.

### 6.2 Static Analysis in the Distributed Domain

Taylor [42] has developed an algorithm for statically analyzing the synchronous communication of a distributed program. Synchronous communication occurs when the sending process blocks until the message is received by the destination process. Effectively, the rendezvous of the send and receive appears as a distributed assignment, $var = expr$, that
takes place in the context of both processes. The sender evaluates \(expr\), and the receiver stores the value into \(var\).

The transformation of the \(\rightarrow\) relation into the synchronous communication regime only affects condition (2) of the three conditions stated in chapter one for asynchronous communication. All the conditions are repeated for completeness: (1) if \(e\) and \(f\) are events in the same process, and \(e\) happens before \(f\), then \(e \rightarrow f\); (2) if \(e\) and \(f\) are a send and receive pair which rendezvous, consider \(e/f\) as a single event (the rendezvous which effects the distributed assignment) on both the sending and receiving processes; and (3) if \(e \rightarrow f\) and \(f \rightarrow g\), then \(e \rightarrow g\).

Taylor's algorithm matches all possible synchronous communications for the programming language Ada [44]. The following is a discussion of Taylor’s technique as modified (by us) to deal with communicating sequential processes (CSP)[15]. CSP is a well-defined language which supports strictly synchronous communication. The semantics of CSP constructs have been formalized, and sound and relatively complete verification methodologies for CSP are well-established [20, 21, 3]. Two message transmission operations are available in CSP. Process \(P_i\) sends a message, \(msg.out\), to process \(P_j\) by a matching send/receive pair. \(P_i\) executes the send operation \(i!msg.out\), and \(P_j\) executes the receive operation \(i?msg.in\).

As part of the static analysis, each process is represented by an annotated flow graph \(G_i\), which is a modification of a sequential program’s flow graph derived from flow analysis [13]. A distributed program is represented by \(\{G_0, G_1, \ldots, G_{N-1}\}\) such that \(G_i = \{V_i, A_i, r_i\}\) where \(V_i\) is the set of nodes, \(A_i\) is the set of arcs, and \(r_i \in V_i\) is the root node of \(G_i\).

In contrast to a flow analysis flow graph that usually represents all statements, nodes of
$G_i$ represent only the statements necessary for communication analysis. In particular, the following commands are represented by nodes: send and receive communication commands, guards comprised of communication commands, and repetitive and selective constructs comprised of communication commands. In addition, the root node of $G_i$ represents the beginning of $P_i$'s execution (begin node), and the node whose out-degree is zero represents the completion of $P_i$'s execution (end node). Arcs show the possible paths of execution between the nodes, and all paths of $G_i$ are assumed to be executable. Figures 6.1 and 6.2 demonstrate two distributed programs' flow graphs. The horizontal lines of the flow graph represent the nodes.

![Figure 6.1: Flow graphs of a 2 process system](image)

![Figure 6.2: Flow graphs of a 4 process system](image)

For any node $v_i$ of $G_i$, the set of immediate successor nodes is the set of all nodes $v'_i$ for which there exists a path $p$ from $v_i$ to $v'_i$ in $G_i$ such that there is no node $v''_i (v''_i \neq v_i ; v''_i \neq v'_i)$ on the path from $v_i$ to $v'_i$. Succ($v_i$) denotes the set of immediate successors of $v_i$. Figure 6.3 list some of the successor sets for figures 6.1 and 6.2.

Taylor defines a concurrency state $C$ as an ordered $N$-tuple $(v_0, v_1, \ldots v_{N-1})$ where each $v_i$ is a node of $G_i$ or is an inactive marker. Each $v_i$ denotes the next node to be executed in $P_i$ or indicates process inactivity. A concurrency state $C$ has successor concurrency states.

**Figure 6.3:** Successor sets

based on the successor sets of the nodes of $C$. A concurrency state $C'=(v_0', v_1', \ldots, v_{N-1}')$ is a successor of $C$, SUCC($C$), if and only if

1. For all $i, 0 \leq i \leq N - 1$, either
   
   (a) $v_i' \in \text{succ}(v_i)$,
   
   (b) $v_i' = v_i$, or
   
   (c) $v_i = \text{end}$ and $v_i' = \text{inactive}$

2. There exists at least one $v_i'$ which represents application of case a or c.

3. Adherence to the communications semantics of CSP is reflected in the application of the three cases a-c. If $v_i$ is a send or receive command, $v_i$ can not be replaced by an element of succ($v_i$) until the command's matching communication command occurs in the concurrency state. When a matching send/receive occur in the concurrency state, either both or neither are replaced by their respective successor nodes for the successor concurrency state.

A matching send ($v_i$) and receive ($v_j$) in a concurrency state indicates the CSP communication between $P_i$ and $P_j$ can occur. The communication between $P_i$ and $P_j$ is an i/o **rendezvous** between $P_i$ and $P_j$.

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
A nonterminal concurrency state has at least one successor state, and a terminal concurrency state has no successor states. Taylor's concurrency history is a sequence of concurrency states $C_0, C_1, \ldots, C_m$ such that

1. $C_0 = (\text{begin}_0, \text{begin}_1, \ldots, \text{begin}_{N-1})$. $C_0$ represents the initial state of the distributed computation.

2. For $i, 0 \leq i \leq m - 1$. $C_{i+1} \in \text{SUCC}(C_i)$

A proper concurrency history is a finite concurrency history such that $C_m$ has no successors; i.e., $C_m$ is a terminal state. A complete concurrency history of a distributed system is the collection of all possible proper concurrency histories. A directed graph provides a visual representation of a complete concurrency history, where each node of the graph represents a concurrency state. For the distributed program in figure 6.1, the complete concurrency history is shown in figure 6.4.

Relating Taylor's algorithm to previously defined distributed system terminology, we see that each proper concurrency history corresponds to a possible total order of the synchronous communications. A proper concurrency history where $C_m$ does not contain all inactive markers represents an execution that does not allow all the processes to complete their execution. For example, if process $P_i$ executes the receive $j?$, but $P_j$ does not send a message to $P_i$, then $P_i$ hangs on the receive and can not complete execution. The complete concurrency history corresponds to all possible communication patterns since all execution paths are considered possible.
Taylor’s algorithm has been modified and expanded for various distributed system’s applications [27, 45, 22, 8, 26]. We have developed algorithms, motivated by Taylor’s work, designed to identify the LCP and LCP messages in each process for an assert statement.

6.3 Communication Analysis for Asynchronous Message Passing

In this work, the processes of a distributed program are written in the programming language C. The language has been augmented with three commands: async_send, async_recv, and assert. The statements async_send and async_recv are for asynchronous communication between processes and are described in detail in chapter 1. The assert command has the format assert(P) where P is a predicate. The predicate P is a boolean expression over the
variables of the distributed program. Currently, the placement of async_send, async_recv and assert statements is restricted to the main function of the program. In this chapter, the language does allow nested if and if/else constructs, but it does not allow loops. This is done for ease of presentation. Loops are added to the language and handled by our analysis in chapter 7.

Each process \( P_i \) is represented by a control flow graph \( (FG_i) \). A distributed program is represented by \( \{FG_0, FG_1, \ldots, FG_{N-1}\} \) such that \( FG_i = \{V_i, A_i, r_i\} \) where \( V_i \) is the set of nodes, \( A_i \) is the set of arcs, and \( r_i \in V_i \). The root node \( r_i \) represents the start of \( P_i \)'s execution. The nodes of \( FG_i \) represent either computation statements or control constructs of the source code. Assignment, async_send, async_recv, and assert statements are classified as computation statements. The if and else constructs and begin and end delimiters are classified as control constructs. An end node represents the completion of \( P_i \)'s execution. The arcs represent \( P_i \)'s flow of execution. If an arc exists from node \( n \) to node \( n' \), \( n' \) can be executed following the execution of \( n \). Although multiple branches may exist in the flow of execution, all flow of execution will terminate into a single end node.

Consecutive assignment statements that occur between control constructs and other types of computation statements are grouped into one node labeled ASSIGN. The commands async_send, async_recv, and assert are represented by SEND, RECEIVE, ASSERT nodes, respectively. The control constructs if and else are represented by nodes labeled IF and ELSE, respectively. The end of the if side of an if/else is represented by a END_IFSIDE node. The end of an if statement is represented by an END_IF node, and the end of the else side of an if if/else is represented by a END_ELSE node.
Each $FG_i$ is generated by parsing the source code of $P_i$. First a lexical analyzer reads in the source code, and scans this code to recognize tokens. The software tool Lex has been used to produce the lexical analyzer.

The lexical analyzer passes the token to a parser. The tokens are parsed according to the ANSI C grammar that appears in Appendix A. This grammar is LR(1). The software tool Yacc helped produce the parser. The productions of the grammar that are relevant for describing the algorithm for generating the $FG_i$s are `postfix.expression`, `unary.expression`, `assignment.expression`, and `selection.statement`.

Actions are embedded in these productions to call functions that collectively generate the control flow graphs. The algorithm, `Create_FG_i()`, implemented by these function calls, is described. For grouping consecutive assignment statements into one node, each assignment statement of the node is an entry in a linked list, and the assignment node references this linked list. A stack is employed to match the begin and end of control constructs. An entry in the stack is a pointer to a node of $FG_i$. The variable `TopStack` is a pointer to the node referenced by the top entry of the stack. The variable `CrtNode` is a pointer to the current node of $FG_i$. Associated with each node of $FG_i$ are two fields that are for constructing the flow graph. The fields are `HoldPtr` and `AddEdgeFlag`. `HoldPtr` is a pointer to a node of $FG_i$ and `AddEdgeFlag` is a boolean flag. The input for `Create_FG_i()` is the source code of $P_i$, and the output of `Create_FG_i()` is the flow graph $FG_i$.

```c
Create_FG_i() /* Input: P_i; Output: FG_i */
Create the ROOT node of FG_i
CrtNode = ROOT node
if an assignment statement is recognized
    Add assignment statement to the tail of the linked list
```
if an async_send is recognized
  if the linked list is not empty
    AddNode(CrtNode, ASSIGN)  /* for the assignment statements */
    linked list is set to empty
  AddNode(CrtNode, SEND)
if an async_recv is recognized
  if the linked list is not empty
    AddNode(CrtNode, ASSIGN)  /* for the assignment statements */
    linked list is set to empty
  AddNode(CrtNode, RECEIVE)
if an assert is recognized
  if the linked list is not empty
    AddNode(CrtNode, ASSIGN)  /* for the assignment statements */
    linked list is set to empty
  AddNode(CrtNode, ASSERT)
if an if statement is recognized
  if the linked list is not empty
    AddNode(CrtNode, ASSIGN)  /* for the assignment statements */
    linked list is set to empty
  AddNode(CrtNode, IF)
  Push CrtNode onto the stack
  TopStack = CrtNode
if an else is recognized
  AddNode(CrtNode, END_IFSIDE)
  if the linked list is not empty
    Set field in CrtNode to point to linked list
    linked list is set to empty
  TopStack.HoldPtr = CrtNode  /* Set HoldPtr of the IF node to the */
  /* address of the END_IFSIDE */
  CrtNode = top entry of the stack
  CrtNode.AddEdgeFlag = true  /* Flag an edge needed from END_IFSIDE node */
  /* to the first node following END_ELSE node */
if the end of the else side of an if/else is recognized
  AddNode(CrtNode, END_ELSE)  /* for the ending of the else side */
  if the linked list is not empty
    Set field in CrtNode to point to linked list
    linked list is set to empty
  CrtNode.HoldPtr = TopStack.HoldPtr  /* Move the address of the END_IFSIDE */
  /* node to the END_ELSE node */
  CrtNode.AddEdgeFlag = true  /* Flag an edge will be needed from END_IFSIDE */
  /* node to the first node following END_ELSE node */
  Pop the stack
if the end of an if statement is recognized
  AddNode(CrtNode, END_IF)  /* for the ending of the if statement */
  if the linked list is not empty
Set field in \textit{CrtNode} to point to linked list
linked list is set to empty
\begin{verbatim}
CrtNode.HoldPtr = TopStack /* Set the HoldPtr of END_IF node */
/* to the address of the IF node */
CrtNode.AddEdgeFlag = true /* Flag an edge will be needed from the IF node */
/* to the first node following the END_IF node */
\end{verbatim}

Pop the stack
\begin{verbatim}
if the current control construct or statement is not recognized
Generate an error and halt
if the end of the source code is recognized
AddNode(CrtNode, END)
\end{verbatim}
If the linked list is not empty
Set field in \textit{CrtNode} to point to linked list
linked list is set to empty
\textbf{end algorithm}

The algorithm \textbf{Create}.	extit{FG}_{1}() calls the algorithm \textbf{AddNode}().

\textbf{AddNode}(CrtNode, type)
\begin{verbatim}
NewNode = Allocate a node
Create a directed edge from CrtNode to NewNode
if CrtNode.AddEdgeFlag
Create a directed edge from the node CrtNode.HoldPtr to NewNode
/* An edge is added either from END_IFSIDE or IF node to NewNode */
if type = ASSIGN
Set field in NewNode to point to assignment linked list
CrtNode = NewNode
\end{verbatim}
\textbf{end algorithm}

When a node is added to \textit{FG}_{1}, if the previously added node is the end of the else side of an if/else, the END_IFSIDE and END_ELSE nodes must both have an edge to this newly added node. Figure 6.5 shows the adding of \textit{NewNode}. The dashed lines indicate the edges \textbf{AddNode}() creates to \textit{NewNode}. The END_ELSE is \textit{CrtNode} so the edge from END_ELSE to \textit{NewNode} is added by the second line of \textbf{AddNode}(). But creating the edge from END_IFSIDE to \textit{NewNode} is more complicated. When END_IFSIDE is added to \textit{FG}_{1},
the address of this node is stored in the IF node. This is accomplished with the following line from \texttt{Create\_FG\_i}():

\texttt{TopStack.HoldPtr = CrtNode}

When the END\_ELSE node is added, the address of the END\_IFSIDE node is moved from the IF node to the END\_ELSE node. This is accomplished with the following line from \texttt{Create\_FG\_i}():

\texttt{CrtNode.HoldPtr = TopStack.HoldPtr}

By moving the address of the END\_IFSIDE, when a new node is added and \texttt{CrtNode} is equal to END\_ELSE, the address of the END\_IFSIDE node is available in \texttt{CrtNode} to add the edge from END\_IFSIDE to \texttt{NewNode}. The flag \texttt{AddEdgeFlag} of the END\_ELSE node is set to true to indicate that function \texttt{AddNode()} should add an edge from the END\_IFSIDE node to \texttt{NewNode}.

\begin{figure}
\centering
\includegraphics[width=0.5\textwidth]{if_else_flowgraph}
\caption{if/else portion of control flow graph}
\end{figure}
CHAPTER 6. STATIC ANALYSIS

Figure 6.6: if portion of control flow graph

Figure 6.7: Flow graphs for a simple 3 process system
Figure 6.6 shows the adding of a new node when CrtNode is a END_IF node. When the END_IF node is created, the address of the IF node, which is available on top of the stack, is stored in the END_IF node. This is accomplished with the following line from CreateFG():

\[ \text{CrtNode.HoldPtr} = \text{TopStack} \]

When NewNode is added to FG, the address of the IF node is available in CrtNode so that an edge from the IF node to NewNode can be created by AddNode(). The flag AddEdgeFlag of the END_IF node is set to true to indicate that function AddNode() should add an edge from the IF node to NewNode. Figure 6.7 is the resulting control flow graphs for the source code of figure 4.2. Another example of a flow graph is figure 6.9 which is the result of one process's source code with nested if constructs shown in figure 6.8.

\[ P_i : \]
\[
\{ \\
\quad a = \text{random number} \\
\quad b = a -1 \\
\quad \text{if } (a > 1) \{ \\
\quad \quad \text{if } (b > 1) \{ \\
\quad \quad \quad \text{async_send(0, a)} \\
\quad \quad \quad b = b * 2 \\
\quad \quad \} \\
\quad \quad \text{else} \{ \\
\quad \quad \quad \text{async_recv(0, b)} \\
\quad \quad \quad a = b * 2 \\
\quad \quad \} \\
\quad \} \\
\quad a = b \\
\}
\]

Figure 6.8: $P_i$'s source code
Figure 6.9: $FG_i$
As we know from the definition of $F G_i$, the nodes of $F G_i$ represent syntactic constructs in the source code of $P_i$. The execution of $P_i$ may be viewed as a traversal of $F G_i$, starting at the root node and ending at the end node. An event in the execution of $P_i$ corresponds to the locus of control passing through a node of $F G_i$. In the remaining discussion of the flow graphs, the symbol representing a node of $F G_i$ is also used to represent the event corresponding to the execution of the source associated with that node. The context of the use of the symbol determines whether it is representing a node of $F G_i$ or an event. For example, if the context is $a \rightarrow b$, the symbols $a$ and $b$ represent events.

We make use of the following properties of a $F G_i$.

**Property 6.1** A path exists from node $a$ to node $b$ in $F G_i$ if and only if $a \rightarrow b$ when both $a$ and $b$ are executed.

Proof.

**PART 1.** If a path exists from node $a$ to node $b$, then $a \rightarrow b$ when both $a$ and $b$ are executed.

**Case 1.** First consider a process's source code in which no if or if/else statements exist. The resulting control flow graph contains only nodes of type ROOT, ASSIGN, SEND, RECEIVE, ASSERT and END, and one path exists from the ROOT node to the END node. Since execution must follow the edges in $F G_i$, a path from $a$ to $b$ implies $a \rightarrow b$.

**Case 2.** Now consider the case in which if and if/else constructs exist. According to the construction algorithm, flow graphs of the form shown in figure 6.10 are generated for an if control construct and an if/else control construct.
For the if control construct, the branch of control resulting from the falsifying of the if statement is the edge from the IF node to S2. When the condition of the if statement evaluates to false, the statements represented by S2 are executed next, and therefore IF $\rightarrow$ S2. Let node $a$ occur before the IF node in $FG_i$, and let node $b$ occur after S2 as are shown in figure 6.10. Two paths exist from node $a$ to node $b$. Independent of which path is followed in an execution $P_i$, $a \rightarrow b$.

![Diagram](image)

**Figure 6.10: if and if/else flow graphs**

Next consider the if/else control construct. For the branch resulting from a true evaluation of the condition of the if/else, a path is created by Create_FGi() from the IF node to the END_IFSIDE and from the END_IFSIDE to S5. If the condition evaluates to true, the statements represented by S3 are executed.
then the statements represented by S5 are executed. Therefore, IF → S3 → END_IFSIDE → S5. For the branch resulting from a false evaluation of the if statement, a path exists from the IF node to the ENDELSE and from the ENDELSE to S5. If the condition evaluates to false, IF → S4 → ENDELSE → S5. Let node a occur before the IF node in FGi, and let node b occur after S5 in FGi as are shown in figure 6.10. Two paths exist from node a to node b. Independent of which path is followed in an execution Pi, a → b.

PART 2. If a → b when both a and b are executed, then a path exists from node a to node b in FGi.

Assume a → b but that a path does not exist from node a to node b in FGi. Two cases can exist in FGi such that a path does not exist from node a to node b.

1. there exists a path from node b to node a. or

2. node a occurs in one branch of a if/else and node b occurs in the other branch of the if/else.

If a path exists from node b to node a, we know from part 1 of this proof that b → a when both b and a are executed. This contradiction stands in to our assumption that a → b. therefore a path cannot exist from b to a. Now consider case 2. Only one branch of the if/else will be executed for any execution of Pi. Therefore, a ≠ b. So we can conclude that if a → b, a path exists from node a to node b.
Property 6.2 Each path of $FG_i$ from ROOT node to the END node represents an execution of $P_i$.

Proof. Assume there exists a path from the root node to the end node that does not represent an execution of $P_i$. For such a path to exist, there must exist at least two nodes $v$ and $v'$ where $v$ is a parent of $v'$, and it is not possible that $v \rightarrow v'$ for any execution of $P_i$. This is a contradiction of property 6.1. ■

Property 6.3 For each path, the occurrence of the nodes in the path represents the total order of events if this path is executed.

Proof: For each statement and control construct of the source code, a node is generated in $FG_i$ (algorithm Create FG_i()). From this observation of Create FG_i() and properties 6.1 and 6.2, it follow that this property is true. ■

Property 6.4 $FG_i$ represents all execution paths of $P_i$.

Proof. This property may be falsified under two conditions:

CONDITION 1. Flow graph $FG_i$ only represents a subset of execution paths of $P_i$. We know from Create FG_i() that every statement and control construct is represent in $FG_i$.

For a path not to be represented in $FG_i$, one or more directed edges between nodes are omitted. Three cases exist when an edge can be omitted:

1. an edge from current node to new node is not added,
2. an edge from END_IFSIDE node to first node following the END_ELSE node is not added, or

3. an edge from IF node to first node following the END_IF node is not added.

For any of these cases to occur, the AddNode() algorithm is contradicted.

**CONDITION 2.** $FG_i$ represents an invalid execution of $P_i$. For this to be true, at least one path from the ROOT node to the END node represents an invalid execution of $P_i$. This contradicts property 6.2.

For each communication node, $v$, of $FG_i$, an immediate successor set $S(v)$ is determined from $FG_i$. Node $v'$ is an immediate successor of node $v$ if

1. there exists a path from $v$ to $v'$,

2. $v'$ is a communication node or END node, and

3. there does not exist a communication node $v''$ on the path from $v$ to $v'$ such that $v'' \neq v'$.

**Concurrency communication states (CCSs)** are generated from the flow graphs $\{FG_0, FG_1, \ldots, FG_{N-1}\}$ of the constituent processes of the distributed system. Each CCS is an ordered $N$-tuple $(v_0, v_1, \ldots, v_{N-1})$ where $v_i$ is the root node of $FG_i$, a communication node of $FG_i$, or the END node of $FG_i$. In the examples, an underscore denotes the END node. If $v_i$ is a communication node, $v_i$ denotes the next communication command to be executed in $P_i$. The communication commands of a CCS represent the events that may
occur concurrently. Not all communication commands are ready to be executed: i.e., a receive is not ready if its corresponding send has not been executed. All the communication commands of a $CCS$ that are ready to execute are concurrent. A series of $CCS$s are generated, as described shortly, to mimic the execution of the distributed system represented by $\{FG_0, FG_1, \ldots, FG_{N-1}\}$. Collectively, a tree, $H$, of $CCS$s is generated that represents all the possible partial orders $\mathcal{P}$ of the distributed system. Figure 6.11 is an example of an $H$ tree where each node of the tree represents a $CCS$. The concurrency among the communication events is preserved in $H$ by not imposing a total order on the concurrent events.

Associated with each send command in a $CCS$ is a counter. If $v_i$ is a send to $P_j$, the counter associated with $v_i$ is how many messages have been sent to $P_j$ including this send. Assume we have a four process system, and $v_1 \in CCS$ is equal to $5$:async_send(0). This five means four messages have been sent collectively to $P_0$ from $P_1, P_2$ and $P_3$ prior to this message. Associated with each receive command whose matching send command has already been executed is also a counter. If $v_j$ is a receive command and has an associated counter, the counter is how many messages have been received by $P_j$ including the message received with $v_j$.

The initial concurrency communication state, $CCS_0$, contains the root node of each flow graph $\{FG_0, FG_1, \ldots, FG_{N-1}\}$, $CCS_0 = (r_0, \ldots, r_{N-1})$. Successor $CCS$s of $CCS_0$ are determined from $S(r_i), 0 \leq i < N$. The successors of $CCS_0$ are a set of concurrency communication states denoted by $SUCC(CCS_0)$. The following steps determine $SUCC(CCS_0)$:

1. Generate a successor of $CCS_0$ by replacing each $r_i$ with an element of $S(r_i)$; i.e.,
CHAPTER 6. STATIC ANALYSIS

\[ CCS = (v_0, \ldots, v_{N-1}) \] is an element of \( \text{SUCC}(CCS_0) \) if each \( v_i \) is an element of \( S(r_i) \).

2. Generate \( \text{SUCC}(CCS_0) \) by repeating step 1 until all unique \( CCSs \) are generated from the root nodes' immediate successor sets. The number of successor \( CCSs \) of \( CCS_0 \) is

\[ |S(r_0)| \cdot \ldots \cdot |S(r_{N-1})| = |\text{SUCC}(CCS_0)| \]

A \( CCS \), where each \( v_i \) is a communication node or an inactive marker, has at least one successor. \( CCS' = (v_0', v_1', \ldots, v_{N-1}') \), if \( CCS \) has at least a send command or a \textit{ready} receive command. If node \( n \) of \( H \) represents the concurrency communication state \( CCS \), the successors of \( CCS \) are represented in \( H \) as the children nodes of \( n \). The predecessor of \( CCS \) is represented in \( H \) as the parent (immediate ancestor) of \( n \). A \textit{ready} receive means that the necessary send command for this receive command occurred in the predecessor of the \( CCS \) or in a ancestor of \( CCS \). A message queue, \( Msg.Q_i \), is maintained for each process. If \( v_j \in CCS \) is a send command to \( P_j \), the entry \( j \) is added to the queue \( Msg.Q_i \) following the generation of \( \text{SUCC}(CCS) \). If \( v_i \) is a receive from \( P_j \) and \( Msg.Q_i \) contains a \( j \), the receive is \textit{ready} and the first \( j \) in \( Msg.Q_i \) is removed.

Associated with each \( Msg.Q_i \) is a counter that is incremented each time an entry is placed in the queue. The current value of the counter is appended to an entry when it is added to \( Msg.Q_i \). An entry in \( Msg.Q_i \) has the format \(<\text{counter, process id}>\). The value of counter is also appended to the send entry of the \( CCS \) node of \( H \) that generated the entry in \( Msg.Q_i \). Send commands that are syntactically identical in a process's source code are distinguished in the \( CCS \) nodes of \( H \) by their associated counter. When a receive \( v_i \) from \( P_j \) is ready, the counter associated with the first \( j \) entry in the queue \( Msg.Q_i \) is appended to the receive entry in the \( CCS \) node of \( H \). Not only are syntactically identical receives
distinguishable, the counter provides a method to match sends with corresponding receives. The use of this counter for matching sends and receives will be seen in a later algorithm.

A CCS may contain multiple sends and ready receive commands. For example, 

\[ CCS = (async\text{-}send(1), async\text{-}send(0), async\text{-}recv(3),-) \]

has the two sends, and a possible ready receive. If \( Msg.Q_2 \) has the entry \(<counter, 3>\) to indicate that \( P_3 \) has sent a message to \( P_2 \) but the message has not been received by \( P_2 \), \( v_2 (v_2 = async\text{-}recv(3)) \) is a ready receive. If \( v_2 \) is a ready receive, the value of \( counter \) is appended to \( async\text{-}recv(3) \) in the \( H \) node. If CCS has no sends and no ready receives, CCS has no successor states. The successor concurrency communication states of CCS, \( SUCC(CCS) \), are determined from the immediate successor sets of CCS's send and ready receive commands. The following steps determine \( SUCC(CCS) \):

1. In CCS, find the send and ready receive commands.

2. Generate a successor of CCS, \( CCS' \), by replacing each \( v_i \) of CCS that is either a send or ready receive command with an element of \( S(v_i) \). If the element of \( S(v_i) \) chosen is the end node, replace \( v_i \) with the inactive marker.

3. Generate \( SUCC(CCS) \) by repeating step 2 until all unique CCS's are generated from the send and ready receive immediate successor sets. For example, if CCS has two sends, \( v_0 \) and \( v_1 \), and one ready receive, \( v_3 \), then the number of successor states of CCS is \( |S(v_0)| \ast |S(v_1)| \ast |S(v_3)| = |SUCC(CCS)| \)

A CCS containing more than one send and/or ready receive commands signifies these commands happen concurrently. If a CCS consists of no send commands and one or more
receive commands, where the receive commands are not ready, the CCS has no successors and is an invalid terminal state of the distributed system. A CCS comprised of all inactive markers is a valid terminal state.

A proper CCS history is a sequence of concurrency states $CCS_0, CCS_1, \ldots, CCS_m$ such that

1. $CCS_0 = (r_0, r_1, \ldots, r_{N-1})$.

2. For all $0 \leq i \leq m - 1$, $CCS_{i+1} \in \text{SUCC}(CCS_i)$, and

3. $CCS_m$ has no successors ($CCS_m$ is a valid or invalid terminal state).

A complete CCS history of a distributed system is a collection of all possible proper CCS histories. The complete CCS history is represented by a directed graph $H = (N, A, r)$ where $N$ is the set of nodes, $A$ is the set of arcs, and $r \in N$ is the root node of the graph.

The nodes represent the CCSs. $r$ represents $CCS_0$, and an arc exists from the node that represents $CCS$ to the node that represents $CCS'$ if $CCS' \in \text{SUCC}(CCS)$. A path from the root node to a node of the graph that has no successors (out-degree is 0) is a proper CCS history. Figure 6.11 is a complete CCS history for the distributed system shown in figure 6.7. The underlined communication events are the sends and ready receive events. The number preceding the communication event is the counter associated with the event.

The following algorithm, $\text{Crt}_H()$, generates the graph $H$ to represent the complete concurrency history. The graph $H$ is built breadth first, that is, one level of the tree is created before the next level is begun. A node of $H$ consists of two entries, $CCS$ and $FGnode[0 \ldots N-1]$. The entry $CCS$ is the $CCS$ this node represents. The array entry
Figure 6.11: Tree $H$ for simple 3 process system
FGnode[i] is the node of FG_i that v_i of CCS represents. The array FGnode is set to the appropriate values by algorithm Crt.H() and is used later by algorithm Crt.P0G().

An array of size N of integers is maintained, counter[0], ..., counter[N-1], by algorithm Crt.H() for counting the number of messages that have been sent to each process. The value of counter[i] is the number of messages that have been sent to P_i and the number of entries that have been placed in Msg.Q_i. In addition to the Msg.Q_i queues, another queue CCS.Q is maintained for recording the CCSs that are to be added next to H. An entry in CCS.Q consists of four parts. a CCS, a linked list representing the set SUCC(CCS), the values of the queues Msg.Q_0, ..., Msg.Q_{N-1} that correspond to CCS after SUCC(CCS) has been determined, and the value of array counter that corresponds to CCS after SUCC(CCS) has been determined. The format of an object in the queue is <node, list, Msg.Q_0, ..., Msg.Q_{N-1}, counter>. An entry in the linked list list consist of two two values, CCS and the variable FGnode corresponding to this CCS. The input to Crt.H() is {FG_0, FG_1, ..., FG_{N-1}}, and the output is the tree H.

Algorithm Crt.H() calls function Determine.SUCC() to determine the successors of a CCS and to place the appropriate entries in the Msg.Q queues and CCS.Q queue. Function Determine.SUCC() calls function Generate.SUCC() to generate all the successors of a CCS. The variables employed by function Generate.SUCC() to generate the successors are S.v_i and index. Corresponding to each send and receive node of FG_i is an array S.v_i that contains the successors of node v_i, S(v_i), in FG_i. If v_i is an entry in a CCS, array S.v_i is the successor nodes of v_i. The maximum number of successors of a node is MAXKIDS, and the dimension of each S.v_i is MAXKIDS+1. Each S.v_i array is filled with -1 for
unused entries. Variable $index$ is an array of $N$ integers. Function $\text{Permute}()$ determines a successor of $CCS$ by selecting an index into each $S.v_i$ array for each $v_i \in CCS$ that is a send or ready receive. The array $index$ contains indexes into each $S.v_i$. If $v_i \in CCS$ is a send or ready receive, $index[i]$ is an index into the array $S.v_i$. If $v_i \in CCS$ is neither send nor ready receive, $index[i]$ is a -1 meaning this $v_i$ should not be changed in the successors of $CCS$. Function $\text{Generate.SUCC}()$ calls function $\text{Permute}()$ to obtain the indexes for a successor of a $CCS$ and continues to call function $\text{Permute}()$ until all successors of a $CCS$ are generated.

The following are useful properties of $H$. In proving these properties, the function $\rho$ maps an event $e$ to the process of the distributed system in which the event occurs.

$$\rho(e) = i \in \Pi \text{ if } e \in P_i$$
**Property 6.5** If

- $v_i$ and $v_j$ are events in the execution of a distributed system,
- $v_i \rightarrow v_j$,
- $v_i \in CCS$ and $v_i$ is a send or ready receive and
- $v_j \in CCS'$ and $v_j$ is a send or ready receive.

then $CSS$ is an ancestor of $CCS'$.

**Case 1** For $\rho(v_j) = \rho(v_i)$.

Proof by induction.

**Basis.** If

- $v_i \in CCS$,
- $v_i$ is a send or ready receive,
- $CCS$ occurs on level $l$ of $H$,
- $v_j \in S(v_i)$, and
- $v_j \in CCS'$

then $CSS'$ occurs on level $l + 1$.

Proof. We know that the SUCC($CCS$) are children of $CCS$ in $H$. According to the construction of $H$, SUCC($CCS$) is determined with the $S(v_i)$ for each $v_i$ that is send or ready receive. Node $v_j$ is represented in at least one $CCS' \in SUCC(CCSCS)$ which occurs on the next level, $l + 1$, of the tree $H$. 

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
**Inductive Hypothesis.** If

- \( v_i \in CCS \),
- \( v_i \) is a send or ready receive.
- \( CCS \) occurs on level \( l \) of \( H \).
- \( v_i \rightarrow v_k \).
- \( \rho(v_i) = \rho(v_k) \), and
- \( v_k \in CCS'' \).

then \( CCS'' \) occurs on level \( l + n \) for \( n > 2 \).

**Inductive Step.** If

- \( v_k \) is a send or ready receive.
- \( v_j \in S(v_k) \), and
- \( v_j \in CCS' \)

then \( CCS' \) occurs on level \( l + n + 1 \).

Proof. We know from the inductive hypothesis that \( CCS'' \) occurs on level \( l + n \) and that \( CCS'' \) is an ancestor of \( CCS \). Since \( v_j \in S(v_k) \), we know from the basis that \( CCS' \) occurs on level \( l + n + 1 \). We can conclude that \( CCS' \) is an ancestor of \( CCS \).

**Case 2. For** \( \rho(v_j) \neq \rho(v_i) \).

Proof. Since \( v_i \rightarrow v_j \), we know from lemma 5.4 there exists a non-repetitive communication path from \( P_i \) to \( P_j \) from a send of \( P_i \) that happens after \( v_i \) (or \( v_i \) is this send) and a receive of \( P_j \) that happens before \( v_j \) (or \( v_j \) is this receive). Let \( NCP = e_i^0,\ldots,e_j^t \)
be this non-repetitive communication path. Two possibilities exist for $v_i$: either $v_i$ and $e_i^0$ are the same event, or $v_i$ occurs before $e_i^0$. Two possibilities exist for $v_j$, either $v_j$ and $e_j^t$ are the same event or $v_j$ occurs after $e_j^t$. In the remaining proof we assume without loss of generality that $v_i$ and $e_i^0$ are the same event and $v_j$ and $e_j^t$ are the same event.

The events of the path $NCP$ correspond to one or more messages. Consider the following 2 cases:

**CASE 2.A.** $NCP$ corresponds to one message.

Event $v_i$ is the sending of a message to $P_j$, and $v_j$ is the corresponding receive of the message from $P_j$. Let the following be true for the nodes $CCS$ and $CCS'$ of $H$: $v_i \in CCS$ and $v_j \in CCS'$. According to the construction of $H$, when $v_j$ is ready, the $i$ entry in $Msg.Q_j$ corresponds to $v_i$. For the $i$ that corresponds to $v_i$ to be in $Msg.Q_j$, $CCS$ must be an ancestor of $CCS'$.

**CASE 2.B.** $NCP$ defines two or more messages.

Let $NCP = e_i^0, e_k^m, e_{k+1}^{m+1}, e_{k+2}^{m+2}, \ldots, e_j^t$, where $m+2 < t$ and $e_i^0 \in CCS$ and is a send, $e_k^m \in CCS''$ and is a receive, $e_{k+1}^{m+1} \in CCS'''$ and is a send, $e_{k+2}^{m+2} \in CCS'''$, and is a receive, and $e_j^t \in CCS'$ and is a receive. We know from case 1 that for events $e_k^m, e_{k+1}^{m+1}$ of $NCP$, where $e_k^m \in CCS''$ and $e_{k+1}^{m+1} \in CCS'''$, that $CCS''$ is an ancestor of $CCS'''$. We know from case 2.a that for events $e_{k+1}^{m+1}, e_{k+2}^{m+2}$ of $NCP$, where $e_{k+1}^{m+1} \in CCS'''$ and $e_{k+2}^{m+2} \in CCS'''$, that $CCS'''$ is an ancestor of $CCS'''$. Therefore, $CCS''$ is an ancestor of $CCS'''$. If $e_k^m$ is the receive event immediately following $e_i^0$ in $NCP$, then from case 2.a we know that $CCS$ is an
ancestor of $CCS''$. Therefore, $CCS$ is an ancestor of $CCS'''$. If $e_{i}^{m+2}$ is the send immediately preceding $e_{j}^{l}$ in $NCP$, then from case 2.a we know $CCS'''$ is an ancestor of $CCS'$. We conclude that $CCS$ is an ancestor of $CCS'$.

\[\]

**Property 6.6** The sends and ready receives of a $CCS$ are concurrent.

Proof. Assume for $v_{i}, v_{j} \in CCS$ that $v_{i} \rightarrow v_{j}$. This contradicts property 6.5.

**Property 6.7** If $CCS$ is an ancestor of $CCS'$. $v_{i} \in CCS$ and $v_{j} \in CCS'$. and $v_{i}$ and $v_{j}$ are either sends or ready receives, then $v_{i} \rightarrow v_{j}$ if one of the following is true:

CASE 1. $\rho(v_{i}) = \rho(v_{j})$

CASE 2. $v_{i}$ is send to $P_{j}$, $v_{j}$ is a ready receive from $P_{j}$, and the next $i$ entry in $Msg.Q_{j}$ corresponds to $v_{i}$.

CASE 3. $v_{i} \rightarrow v_{k}$ and $v_{k} \rightarrow v_{j}$ where $v_{k} \in CCS''$ such that $v_{k}$ is either a send of ready receive. $CCS$ is an ancestor of $CSS''$, and $CSS''$ is an ancestor of $CCS'$.

Proof.

CASE 1.

For $v_{j}$ to occur in $CCS'$ that is a descendant of $CCS$. $v_{j} \in S(v_{i})$ or $v_{j} \in S(S(...S(v_{i})...))$ where the nesting of immediate successor sets is two or greater.

Therefore $v_{i} \rightarrow v_{j}$.
CHAPTER 6. STATIC ANALYSIS

CASE 2.

According to the algorithm for constructing \( H \), for \( u_j \) to be a ready receive and the next \( i \) entry in \( Msg.Q_j \) to correspond to \( v_i \), \( v_i \) must happen before \( v_j \).

CASE 3.

This follows directly from the transitive property of the happens before relationship.

\[
\square
\]

We know from property 6.6 that the sends and ready receives of a \( CCS \) are concurrent. We can deduce concurrent sends and ready receives that occur in different \( CCS \)s. Entries \( v_i \) and \( v_j \) are concurrent if \( v_i \in CCS \), \( v_j \in CCS' \), \( v_i \) and \( v_j \) are either sends or ready receives. \( CCS \) is an ancestor of \( CCS' \), and \( v_i \not\rightarrow v_j \).

Before stating and proving the next property, lemma 6.1 is established. The execution of a communication event in \( P_i \) represented by node \( n \) in \( FG_i \) is possible if there exists at least one path from the root node to \( n \) such that the communication events occurring in the path prior to \( n \) are either sends or ready receives in \( H \). In other words, the communication event of node \( n \) has a possibility of being executed if the communication events that occur prior to it are executed. If a receive is possible, its execution is then dependent on a message being sent, and the receive is labeled as ready when the necessary message is sent. If the necessary message is not sent, the receive does not become ready and does not execute. If a send is possible, it executes since a send's execution is not dependent on the occurrence of a communication event in another process.
An example of a possible receive event and an impossible receive event is shown in figure 6.12. In $FG_2$ there exists a path from the root node to the first `async_recv(1)`. We know from the construction of $H$ that `async_send(0)` will be an element of a node of $H$, and `async_send(1)` will be an element of a node of $H$. The first `async_recv(1)` of $FG_2$ will occur in a node of $H$ as a receive, but this receive will not be ready since the sending of a message from $P_1$ to $P_2$ does not exist. This receive occurs as an entry in an $H$ node to represent the receive waiting to execute. The communication commands of $P_2$ prior to the first `async_recv(1)` are executed, and `async_recv(1)` is possible although it will not
execute. Since the first \texttt{async\_recv(1)} of \texttt{P\_2} cannot execute, the second \texttt{async\_recv(1)} of \texttt{P\_2} will not occur in a node of \texttt{H} and is therefore impossible.

**Lemma 6.1** If node \texttt{n} of \texttt{FG\_i} is a communication node and the execution of \texttt{n} is possible, then \texttt{n} is a send or receive in at least one node of \texttt{H}.

**Proof.**

**Basis.**

If node \texttt{n} is a successor of the root node of \texttt{FG\_i}, \texttt{n} $\in$ \texttt{S(r\_i)}, then \texttt{u\_i} = \texttt{n} for at least one \texttt{CSS} $\in$ \texttt{SUCC(CCS\_0)}. \texttt{CCS\_0} occurs on level 0 of \texttt{H}. therefore each \texttt{CCS} $\in$ \texttt{SUCC(CCS\_0)} occurs on level 1 of \texttt{H}.

**Proof.** According to the construction of \texttt{H}, the \texttt{SUCC(CCS\_0)} is determined by \texttt{S(r\_i)} for all \texttt{i}. Node \texttt{n} of \texttt{FG\_i} is represented in at least one \texttt{CCS} $\in$ \texttt{SUCC(CCS\_0)}.

**Inductive Hypothesis.**

If node \texttt{n\_'} is a communication node of \texttt{FG\_i}, \texttt{n\_'} is an immediate predecessor of node \texttt{n} in \texttt{FG\_i}, and the execution of \texttt{n\_'} is possible, then node \texttt{n\_'} is represented in \texttt{CCS\_'} on level \texttt{i} of \texttt{H}.

**Inductive Step.**

If node \texttt{n} $\in$ \texttt{S(n\_')} and the execution of node \texttt{n} is possible, then node \texttt{n} is represented in at least one \texttt{CCS} $\in$ \texttt{SUCC(CCS\_')} on level \texttt{i + 1} of \texttt{H}.

**Proof.** From the inductive hypothesis, we know \texttt{n\_'} is represented in node \texttt{CCS\_'} on level \texttt{i} of \texttt{H}. For the execution of node \texttt{n} to be possible, node \texttt{n\_'} is either a send or ready receive element of \texttt{CCS\_'}.
In the construction algorithm, SUCC(CCS') is determined by S(v_i) for all i of CCS' that are sends or ready receives. Let v'_i = n' in node CCS'. Since v'_i is a send or a ready receive of CCS' and n ∈ S(v'_i), we can conclude that node n is represented in at least one CCS ∈ SUCC(CCS') on level i + 1 of H.

Property 6.8 The tree H derived from \{ FG_0, ..., FG_{N-1} \} represents all partial orders of the distributed system represented by \{ FG_0, ..., FG_{N-1} \}.

Proof.

1. From properties 6.1, 6.3, and 6.4, we know each FG_i represents all execution paths of P_i, and the occurrence of the nodes of a path of FG_i represents the total order of events of P_i.

2. From properties 6.5 and 6.7, we know all the happens before relationship among local and non-local events of the distributed system are correctly represented in H.

3. From lemma 6.1, we know that if the execution of a communication node of FG_i is possible, then the communication event is represented in H.

From (1), (2) and (3), we can conclude all possible executable events of each process are represented in H, and all happens before relationships among these events are correctly represented in H. Therefore all partial orders of the distributed system are represented in H.
In some cases, two or more branches of $H$ represent the same partial order. Consider the portion of tree $H$ for a four processor system in figure 6.13. In this example, the receives of the CCSs are not ready. The sends of each CCS are replaced in the child CCSs with an inactive marker. Both leaf node branches indicate that $P_0$ does not complete execution. The two branches shown represent the same partial order. From the tree $H$, a partial order graph, $POG$, is constructed that combines branches that represent the same partial order into one branch. Also, only the sends and receives that are executed in a partial order are represented in the $POG$. In other words, the sends and ready receives are presented in the $POG$.

![Figure 6.13: Same partial orders](image)

A $POG$ is a directed graph $(N, A, s)$ where $N$ is the set of nodes, $A$ is the set of arcs, and $s \in N$ is the root node of $POG$. The nodes of the $POG$ are generated from $H$'s nodes such that the $POG$ nodes represent the sends and ready receives command of the $H$ nodes.

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
In the remaining discussion of POG nodes, the following format of an entry is a POG node is adapted for conciseness. A send entry has the format \( c : iSj \) where \( c \) is the counter, \( i \) is the process executing the send and \( j \) is the destination process. A ready receive entry has the format \( c : iRj \) where \( c \) is the counter, \( i \) is the process executing the receive and \( j \) is the sender. The POG is constructed by traversing \( H \) breath first, starting at the the root node of \( H \) and generating the nodes of the POG in breath first order. The algorithm for constructing the POG determines whether CCSs have equivalent send and ready receive communication entries. CCS\(_1\), ..., CCS\(_t\) have equivalent communications if the following conditions are true:

1. If at least one CCS\(_{q:1 \leq q \leq t}\) contains one or more send and/or ready receive commands.
2. If \( v_i \) is a send command of CCS\(_{q:1 \leq q \leq t}\), then each \( v_i \) in all CCS\(_{r:1 \leq r \leq t}\) is the same\(^1\) send command.
3. If \( v_i \) is a ready receive command of CCS\(_{q:1 \leq q \leq t}\), then each \( v_i \) in all CCS\(_{r:1 \leq r \leq t}\) is the same receive command and is a ready receive.

If CCS\(_i\) and CCS\(_j\) have equivalent communication commands, the equivalent communication commands of CCS\(_i\) and CCS\(_j\) are all the send and ready receive commands that occur in CCS\(_i\) and CCS\(_j\).

The algorithm for constructing the POG relies on the function \textit{EQUIV()}\footnote{Same meaning each \( v_i \) represents the same node of \( FG_i \) and the counters are equal.}. The input to \textit{EQUIV()} is a set of \( H \) nodes, \textit{node.set}, and the return value is a subset of \textit{node.set}. If \textit{node.set} contains two or more nodes that have equivalent communication commands, \textit{EQUIV()} re-
turns these nodes, else EQUIV() returns 0. Nodes of $H$ that have equivalent communication commands are called equivalent nodes. If EQUIV() finds a subset of node.set that have equivalent communication commands, EQUIV() removes these nodes from node.set.

If node.set contains two or more equivalent node subsets, EQUIV() nondeterministically returns only one of these subsets. For example, let the CCSs of node.set equal $\{(2:0S1, 3:1R2, 2R0, 3R0), (2:0S1, 3:1R2, 2R1, 3R1), (1:0R1, 1R3, 2:2S0, 3R0), (1:0R1, 1R0, 2:2S0, 3R0)\}$. The first and second entries in node.set are equivalent and the third and forth entries in node.set are equivalent. EQUIV() will return either the nodes corresponding to $\{(2:0S1, 3:1R2, 2R0, 3R0), (2:0S1, 3:1R2, 2R1, 3R1)\}$ or $\{(1:0R1, 1R3, 2:2S0, 3R0), (1:0R1, 1R0, 2:2S0, 3R0)\}$. To select a node from a set of $H$ nodes for testing if a subset of the nodes are equivalent, function EQUIV() calls function Select(). Function Select() randomly picks a node element from a set of nodes, removes the element from the set, and then returns this element.

If the return value of EQUIV() is not NULL, the returned nodes are represented with one node in the POG. This POG node is labeled with the sends and ready receives of the returned nodes.

The POG construction algorithm, Crt.POG(), places information about the newly added nodes of the POG in the queue data structure VisitNodes. An entry in the VisitNodes queue has the format $\langle node.ptr, node.set \rangle$. The entry node.ptr points to a node of the POG, and node.set is a set of one or more $H$ nodes. The set node.SuccSet is a set of $H$ nodes that is built from the successors of equivalent nodes. The string Commos is set to the sends and ready receives of an $H$ node and is for labeling the nodes of the POG. For example if the
CCS of a node is \(1:0S1,3:1S0\), then \(\text{Commos} = "1:0S1,3:1S0"\). The following algorithm constructs the POG from \(H\):

\[
\text{Crt}_P\text{OG}() \\
\text{Initialize queue } Visit\text{Nodes} \text{ to empty} \\
\text{Create root node } S \text{ (labeled root)} \\
\text{Add } <S.SUCC(\text{root node of } H)> \text{ as the first entry in the queue } Visit\text{Nodes} \\
\text{while } (Visit\text{Nodes not empty }) \\
\text{item} = \text{behead}(Visit\text{Nodes}) \quad /\ast \text{ format of item is } <\text{node}\_\text{ptr}. \text{state\_set}> \ast/ \\
\text{POG}_\text{ptr} = \text{item}\_\text{node}\_\text{ptr} \\
\text{node\_set} = \text{item}\_\text{node}\_\text{set} \quad /\ast \text{state\_set} = \{\text{CCS}_1, ... , \text{CCS}_m\}, m \geq 1 \ast/ \\
\text{while } (\text{EQUIV}\_\text{set} = \text{EQUIV}(\text{node\_set}) \neq \emptyset) \\
\text{Commos} = \text{the sends and ready receives of the CCSs of } \text{EQUIV}\_\text{set} \\
\text{Create POG node } N \text{ and label with Commos} \\
\text{Create an arc from node of } \text{POG}\_\text{ptr} \text{ to } N \\
\text{node\_SuccSet} = \emptyset \\
\text{for each node of } \text{EQUIV}\_\text{set} \\
\text{node\_SuccSet} = \text{node\_SuccSet} \cup \text{SUCC}(\text{node}) \\
\text{end for} \\
\text{Add the entry } <N. \text{node\_SuccSet}> \text{ to the tail of } Visit\text{Nodes} \\
\text{node\_set} = \text{node\_set} - \text{EQUIV}\_\text{set} \\
\text{end while} \\
\text{for each node } \in \text{node\_set} \\
\text{if } ((\text{Commos} = \text{sends and ready receives of the CCS of } \text{node}) \neq \text{NULL}) \\
\text{Create POG node } N \text{ and label with Commos} \\
\text{Create an arc from node of } \text{POG}\_\text{ptr} \text{ to } N \\
\text{Add the entry } <N.\text{SUCC}(\text{node})> \text{ to the tail of } Visit\text{Nodes} \\
\text{else} \\
\text{Create POG node } N \text{ and label as END node} \\
\text{Create an arc from node of } \text{POG}\_\text{ptr} \text{ to } N \\
\text{endif} \\
\text{endfor} \\
\text{end while} \\
\text{end algorithm}
\]

The POG represents the causal and concurrent relationship among the communication events. The first four properties of the POG are derived directly from the properties of \( H \).

Property 6.9 If \( e_i \rightarrow e_j \), where \( e_i \) and \( e_j \) are communication events, and \( e_i \) is an entry in node \( N \) of the POG and \( e_j \) is an entry in node \( N' \) of the POG, then \( N \) is an ancestor of \( N' \).

Property 6.10 The communication events represented in a node of the POG are concurrent.

Property 6.11 If POG node \( N \) is an ancestor of POG node \( N' \) and \( e_i \in N \) and \( e_j \in N' \), then \( e_i \rightarrow e_j \) if one of the following is true:

1. \( \rho(i) = \rho(j) \)
2. \(e_i\) is a send to \(P_j\), \(e_j\) is a receive from \(P_i\), and \(e_j\) is the corresponding receive for this send.

3. \(e_i \rightarrow e_k\) and \(e_k \rightarrow e_j\) where \(e_k \in N''\) such that \(N\) is an ancestor of \(N''\) and \(N''\) is an ancestor of \(N'\).

Property 6.12 The POG represents all partial orders.

The construction of the POG prunes the tree \(H\) with the \text{EQUIV()} function so that one branch of the POG from root to leaf node represents an unique partial order \(\alpha \in \mathcal{P}\). The nodes of the POG are minimized from the nodes of \(H\) to represent only the communication commands that occur in an execution of the distributed system. The properties of \(H\) remain true in the POG since the construction does not eliminate or create new information about the occurrence of the communication events.

Lemma 6.2 The construction of the POG from \(H\) preserves the causal and concurrent relationships represented in \(H\).

Proof.

Case 1. Nodes of \(H\) with equivalent communication commands do not exist.

Function \text{EQUIV()} always returns 0 for nodes of tree \(H\); i.e., there exists no nodes of \(H\) that have equivalent communication commands.

Algorithm \text{Crt_POG()} traverses \(H\) in a breath-first order with the use of queue \text{VisitNodes}. The next entry in \text{VisitNodes} represents the next group of nodes in \(H\) to be represented in the POG. Consider creating the nodes and edges of the POG.
CHAPTER 6. STATIC ANALYSIS

NODES.

If a node of \( H, h \), has at least one send or ready receive, the node is represented in the \( POG \) by creating a \( POG \) node and labeling it with the corresponding sends and ready receives of \( h.CCS \).

If a node of \( H \) does not have at least one send or ready receive, a node is not created in the \( POG \) to represent this node. A node of \( H, h \), that does not have at least one send or ready receive means no communication commands are executed after the sends and ready receives of \( h \)'s parent, and therefore node \( h \) does represent any causal or concurrent relationships among events.

EDGES.

If a node of \( H, h \), is represented in the \( POG \) by node \( n \) and if a child of \( h \) is represented in the \( POG \) with node \( n' \), then an edge is created from node \( n \) to node \( n' \) of the \( POG \). Therefore, causal and concurrent relationships among nodes of \( H \) are preserved in the \( POG \). Since all nodes of \( H \) that have at least one send or ready to receive are represented in the \( POG \), all causal and concurrent relationships are preserved.

CASE 2. Nodes of \( H \) with equivalent communication commands do exist.

Function \textit{EQUIV()} finds nodes of \( H \) that have equivalent communication commands.

The nodes that are input to \textit{EQUIV()} are nodes that occur in the same level of \( H \). If the nodes of \( H, \{ h_1 \ldots h_t \} \), are equivalent (the \( CCSs \) have equivalent communication commands) one node \( n \) is created in the \( POG \) to represent these \( t \) nodes and is labeled with the equivalent communication commands. Then set \textit{node.SuccSet} is built so that
node\_SuccSet = SUCC(h_1) \cup \cdots \cup SUCC(h_t). Set node\_SuccSet is placed in the queue VisitNodes for generating the children of node n. Therefore nodes of H that represent the same causal and concurrent relationships are represented as one node in the POG, and all causal and concurrent relationships that are represented by the successor nodes of \{ h_1 \ldots h_t \} will be represented in the POG as children of n.

![Diagram](image)

**Figure 6.14**: 2 possible POGs

A partial order $\alpha \in \mathcal{P}$ is represented in the POG by a path beginning at the root node and ending at a leaf node of the tree. The process of generating the POG guarantees
that there exists only one possible representation of a partial order in the POG. Figure 6.14 is the time-space diagram of a distributed system's execution and the two possible unique path representations of the partial order defined by the system's execution. From property 6.11 we can determine from either of the two paths the following relationships: $1:0S1 \rightarrow 1:0S2, 1:0S1 \rightarrow 1:1R0, 1:0S2 \rightarrow 1:2R0$, and $1:0S1$ and $1:0S2$ are concurrent. Of the two paths shown in figure 6.14, only the path to the left is generated by the Crt_POG() algorithm. Since the POG is derived from $H$, algorithm Crt_H() dictates the path that will occur in the POG for a partial order. The $H$ generated by algorithm Crt_H() is shown in figure 6.15 for the execution shown in figure 6.14. The left path in 6.14 is generated from this $H$.

**Lemma 6.3** For partial order $\alpha \in \mathcal{P}$, there exists one possible representation of $\alpha$ in the POG.

**Proof.**

A partial order is represented in the POG by a path beginning at the root node and ending at a leaf node of the tree.

Assume there exist two different representations of $\alpha$ in the POG, thus there must exist two differing paths from the root node to a leaf node that correspond to $\alpha$. For this to occur, $H$ must have at least one path from the root to a leaf node that corresponds to each path of $\alpha$ in the POG (according to algorithm Crt_POG() and lemma 6.2). Let $p$ be one such path of $H$, and let $p'$ be the other path of $H$. The nodes of paths $p$ and $p'$ must differ in the order that the sends and ready receives occur in the path to generate two different
Figure 6.15: $H$ tree

representations of $a$ in the POG (according to algorithm Crt.POG() and function EQUIV()).

For $p$ and $p'$ to differ in this manner, there must exist a node $n$ of $H$ that is common to both paths that has at least two children that mark the differing of paths $p$ and $p'$. Let $c$ be a child of $n$ that corresponds to path $p$ and let $c'$ be a child of $n$ that corresponds to path $p'$. For nodes $c$ and $c'$ to correspond to different paths in the POG, nodes $c$ and $c'$ must consist of different send and ready receives (according to algorithm Crt.POG() and function EQUIV()).
For node \( n \) to have children, node \( n \) must have at least one send or ready receive. Let \( v_i \in n \) where \( v_i \) is a send, \( iSj \). The children of \( n \), \( \text{SUCC}(n) \), are determined by the successors of \( iSj \), \( S(iSj) \). For \( \text{SUCC}(n) = \{c, c'\} \), \( S(iSj) \) must have two entries. For \( S(iSj) \) to have two entries, there must exist two branches in \( FG_i \) from the node of \( FG_i \) that corresponds to \( iSj \) such that each branch includes a successor of \( iSj \). In \( FG_i \), a branch indicates a different total order of events of \( P_i \). Therefore \( c \) and \( c' \) of \( H \) mark the beginning of two different partial orders, and the POG paths that are derived from \( p \) and \( p' \) represent two different partial orders. A contradiction to our assumption has been reached.

Let \( v_i \in n \) where \( v_i \) is a ready receive, \( iRj \). Since \( \text{SUCC}(n) = \{c, c'\} \) occurs under the same conditions as when \( v_i = iSj \), the same contradiction is reached for \( v_i = iRj \).

\(\blacksquare\)

**Property 6.13** Each path of the POG from root node to leaf node represents a unique partial order

**Proof.**

Assume two paths of the POG represent the same partial order. Two cases are possible for this to occur.

**CASE 1**. The two paths are identical.

For this to occur, there must exist a node of the POG that has two children that are identical. This contradicts function EQUIV().

**CASE 2**. The two paths differ but represent the same partial order.

This contradicts lemma 6.3.

\(\blacksquare\)
CHAPTER 6. STATIC ANALYSIS

Figure 6.16: POG derived from $H$ of figure 6.11

Figure 6.16 is the POG of the distributed program in figure 4.2. and this POG is generated from $H$ shown in figure 6.11. Notice that the two partial orders of figure 4.3 are each represented as a path from root to a leaf node in the POG. In particular, the left path of the POG represents $PO_1$, and the right path of the POG represents $PO_2$.

6.4 LCP and LCP' Events

For an event $e_i$, each process's LCP and LCP' events can be determined from the POG.

From theorem 4.1 and lemma 5.1, we know that for a partial order $\alpha$ and event $e_i$, at most
one $CC(e_i)$ exists and this $CC(e_i)$ consists of $LCP$ events which are communication events. The causal global state for event $e_i$ is identified by $CC(e_i)$. From theorem 5.2, we know that by piggybacking state data on the $LCP$ and $LCP'$ events, the $CGState(e_i)$ is available in $P_i$ for event $e_i$.

Before determining the $LCP$ and $LCP'$ events of the assert statement $e_i$, the last $LCP'$ receive event that occurs in $P_i$ must be identified for each execution path of $P_i$ that includes $e_i$. "Last" means the receive event corresponding to the last of the latest causal messages that will piggyback state information to $P_i$ for evaluating the assert statement. Since the assert statement and all possible executions of $P_i$ are represented in $FG_i$, the last $LCP'$ event(s) of $P_i$ is(are) identified from $FG_i$.

The algorithm $BouncLAssert()$ determines the last $LCP'$ event(s) of an event. Referring to figure 6.7, note that an async_recv(0) of $P_i$ has two parents. Since a node of $FG_i$ can have more than one parent, the parents of each node are maintained as a linked list of node pointers. The variable $current_list$ is set to this linked list. The variable $NextBranch$ is a stack, and an entry in the stack is a linked list of $FG_i$ node pointers. The variable $Local_LCPs$ is a linked list of $FG_i$ node pointers, and at the completion of the algorithm the entries in this linked list are the last $LCP'$ receive events of an event in $P_i$.

The input to $BouncLAssert()$ is $FG_i$ and $assert\_node$. The variable $assert\_node$ is a pointer to the assert node in $FG_i$. Algorithm $BouncLAssert()$ begins the search for the last $LCP'$ events of $assert\_node$ with the first parent node in $assert\_node$'s $current\_list$. The search continues by traveling up the tree until a receive event is found or the root node is reached. Each possible path from $assert\_node$ to the root node of $FG_i$ is searched for a
CHAPTER 6. STATIC ANALYSIS

receive event. In the case that multiple paths exist from the assert_node to the root node, a different receive.event may be found on each path. If a receive event is found on the path, this receive event is a last LCP' event and is placed in the linked list Local.LCPs, and the search is stopped on this path. The output of the algorithm is Local.LCPs.

Bound.Assert()

/* input: FG, and assert_node */

current_list = the parent nodes of assert_node
NextBranch = NULL
Local.LCPs = NULL
crt_node = first entry in current_list
Remove crt_node from current_list
receive_found = false
do
while (receive_found=false) AND (crt_node ≠ root node of FG)
  if (current_list ≠ NULL)
    Push current_list on the stack NextBranch
  endif
  if crt_node = receive
    Add crt_node to Local.LCPs
    receive_found = true
  else
    current_list = parent nodes of crt_node
    crt_node = first entry in current_list
    Remove crt_node from current_list
  endif
endwhile
if (NextBranch ≠ NULL)
  receive_found = false
  current_list = Pop(NextBranch)
  crt_node = first entry in current_list
  Remove crt_node from current_list
endif
while (NextBranch ≠ NULL)
end algorithm

From Bound.Assert() we have identified the last LCP' events in FGi. The next step is to identify these same events in the FOG. Each entry in Local.LCPs is represented in
the POG at least once if the execution of the receive is possible. To access the POG node that corresponds to an entry in Local-LCPs, it is necessary to know which send and receive commands of the control flow graphs each POG node represents. When creating a POG node, a linked list of pointers is built that identifies the send and/or receive nodes of the control flow graph that the POG node represents. Also, each send or receive node of FG_i has a linked list of pointers to the POG nodes that represent this communication event. For each entry in Local-LCPs, which is actually a pointer to the appropriate receive node in FG_i, the POG node(s) that represent the receive can be accessed.

If an entry in Local-LCPs is represented by a POG node, then this receive is a LCP' event of assert.node in P_i. If an entry in Local-LCPs is not represented by a POG node, then this receive can not be executed and therefore is not an LCP' event.

Continuing with the distributed program shown in figure 4.2, we find the last LCP' events of P_i from figure 6.7 using algorithm Bound_Assert(). Process P_i has only one such message. async_recv(0). This is the async_recv(0) that immediately precedes the assert statement in FG_i. Two nodes of the POG represent this communication command, one for partial order PO_1 and the other for partial order PO_2. These two POG nodes are shown in figure 6.17 with double circles.

From theorem 5.2 we know for assert event e_i there exist a non-repetitive communication path from each LCP event to an LCP' event of P_i that consists of LCP and LCP' events. The algorithm Find_LCPs() accesses the POG to find these LCP' and LCP events for the assert event e_i. For each partial order branch of the POG corresponding to an entry in Local-LCPs, the algorithm traverses the branch in an upward direction beginning with
the receive event of Local.LCPs up to possibly the root node to find these non-repetitive communication paths. Since the branch is traversed upward, the receives (LCP's) of the messages are encountered before the matching sends (LCPs).

When a receive event, \(c:jRk\), is encountered in a POG node, it is a candidate LCP' event if:

1. a non-repetitive communication path has been found from \(P_j\) to \(P_i\) that occurs after \(c:jRk\) and a non-repetitive communication path from \(P_k\) to \(P_i\) has not been found, or
2. the receive event is an event of $P_i$ and a non-repetitive communication path from $P_k$ to $P_i$ has not been found.

The reason for candidate is the receive event $c:jRk$ is not an $LCP'$ event of $P_j$ if another non-repetitive communication path from $P_k$ to $P_i$ is found before\(^2\) the matching send of $c:jRk$ is encountered in the $POG$.

When a send event, $c:jSk$, is encountered in the $POG$, it is an $LCP$ event if:

1. the matching receive, $c:kRj$, has been encountered, and
2. receive event, $c:kRj$, is a candidate $LCP'$ event.

Six data structures are employed by algorithm $\text{FindLCPs}()$ to find the $LCP$ and $LCP'$ events when traveling up a branch of the $POG$. Three of the six data structures are sets of process numbers. These sets are $\text{FoundProcs}$, $\text{Sends}$, and $\text{RecwoSends}$. The set $\text{FoundProcs}$ contains the entry $j$ if the piggybacking message for $P_j$, consisting of the send event of $P_j$ and the matching receive event, has been determined from the $POG$. Set $\text{Sends}$ contains the entry $j$ if the send event for piggybacking data from $P_j$ has been found. Set $\text{RecwoSends}$ contains the entry $j$ if the receive end of a piggybacking message has been found for $P_j$ but the matching send has not. The other three data structures are queues: $\text{RwoSQ}$, $\text{SendQ}$ and $\text{RecvQ}$. The queue $\text{RwoSQ}$ contains entries for receive commands whose matching send command has not been found in the $POG$. An entry in $\text{RwoSQ}$ has the format $<c, i, j, POGnode>$ where $c$ is the counter, $i$ is process number of the receiver,

\(^2\)Before in this context meaning the path happens after the matching send since the $POG$ is traversed upward.
j is the process number of the sender, and POGnode is a pointer to the POG node that contains the receive. The queue SendQ contains an entry for each LCP send event, and an entry has the format <c, j, POGnode> where c is the counter, j is the process number of the sender and POGnode is a pointer to the POG node containing the send event. The queue \( \text{RecvQ} \) contains an entry for each \( \text{LCP}' \) receive event, and an entry has the format <c, j, POGnode> where c is the counter, j is the process number of the receiver and POGnode is a pointer to the POG node containing the receive event.

\text{endfor}
\]
\[ POGnode = \text{ParentOf}(POGnode) \]

```plaintext
endwhile
endfor
endfor
end algorithm
```

The if statements of the algorithm are complex and require explanation. When a receive event \( c:jRk \) occurs in a \( POG \) node, the following check is made:

\[
\text{if } ((j \in \text{Sends}) \text{ or } (j = i)) \text{ and } (k \notin \text{FoundProcs}) \text{ and } (\text{Rec}_woSend \text{ does not have entry } jRk)\]

The value \( j \) being in the set \( \text{Send} \) indicates a non-repetitive communication path has been found from \( P_j \) to \( P_i \) that occurs after this receive. Any data received by \( P_j \) from receive event \( c:jRk \) can then be piggybacked on the messages of the path to \( P_i \). If \( j = i \), then the receive is a local event of the process evaluating the assert. The data piggybacked on the message of this receive event will be available to the assert statement without having to piggyback the data on additional messages. The value \( k \) being in \( \text{FoundProcs} \) indicates the \( LCP \) and \( LCP' \) events for piggybacking the state information of \( P_k \) have been found, and the message associated with this receive is not needed for piggybacking data from \( P_k \) to \( P_i \). If the if statement evaluates to true, the receive event is a candidate \( LCP' \) event.

Assume \( P_j \) has two or more \( jRk \) receive events, and one \( jRk \) is already inserted in \( RwoSQ \). If the other \( jRk \) receive events are encountered by the algorithm, they should not be considered as \( LCP' \) events since their execution occurs before the \( jRk \) that is represented in \( RwoSQ \). The last condition of the if statement prevents these events from being considered.
When a send event \( c:jS_k \) occurs in a POG node, the following check is made first:

\[
\text{if } (k \in \text{Rec._wo.Sends}) \text{ and } ((\text{Recv.POGnode} = \text{SearchQ}(c,k,j)) \neq \text{NULL})
\]

The value \( k \) being in the Rec._wo.Sends set indicates \( P_k \) has a receive event that is a candidate \( LCP' \) event and the matching send event has not been found. For this send to be the matching send event, the receive for \( P_k \) must be expecting a message from \( P_j \). The function SearchQ() searches the queue RwoSQ for the occurrence of the entry \( \langle c, k, j, POGnode \rangle \). If found, the entry is deleted from RwoSQ and POGnode is returned. If not found, NULL is returned. The if statement evaluating to true indicates this send, \( c:jS_k \), is an \( LCP \) event and the matching receive pointed to by Recv.POGnode is an \( LCP' \) event. The nested if statement checks whether \( k \) should be removed from Rec._wo.Sends.

\[
\text{if } (\text{RwoSQ does not have an entry with } k \text{ as the receiver})
\]

If, after SearchQ() removes the entry corresponding to \( c:jS_k \), RwoSQ has an entry where \( P_k \) is the receiver of a message, then there is a possibility that \( P_k \) has additional \( LCP' \) events. The value \( k \) should remain in Rec._wo.Sends to indicate that receives of \( P_k \) are candidate \( LCP' \) messages. If RwoSQ does not have an entry where \( P_k \) is the receiver of a message, then the value \( k \) is removed from Rec._wo.Sends.

Since we have identified the last \( LCP' \) events of the distributed program shown in figure 4.2, we next identify the \( LCP \) and \( LCP' \) events. For each partial order, the \( LCP \) and \( LCP' \) events are determined with algorithm Find_LCPs(). The steps taken by Find_LCPs() to find the \( LCP \) and \( LCP' \) events of partial order \( PO_1 \) are given. For each iteration of
the algorithm's loop, the variables values are shown. The values of the variables before executing the loop are:

\[
\begin{align*}
Rec\_wo\_Sends &= \{1\} \\
FoundProcs &= \emptyset \\
Sends &= \emptyset \\
i &= 1 \\
RwoSQ &= (<3,1.0,3:1R0>) \\
SendQ &= NULL \\
RecvQ &= NULL \\
POGnode &= 2:1R2
\end{align*}
\]

For the first iteration of the loop, the if statement \(((j \in Sends) \lor (j = i)) \land (k \notin FoundProcs) \land (Rec\_wo\_Sends does not have entry jRk)\) evaluate to true for event 2:1R2. The values of the variables after this iteration are:

\[
\begin{align*}
Rec\_wo\_Sends &= \{1\} \\
FoundProcs &= \emptyset \\
Sends &= \emptyset \\
i &= 1 \\
RwoSQ &= (<3.1,0.3:1R0>, <2.1,2.2:1R2>) \\
SendQ &= NULL \\
RecvQ &= NULL \\
POGnode &= 3:0S1,1:1R0
\end{align*}
\]

For the second iteration of the loop, the if statement \((k \in Rec\_wo\_Sends \land (Recv\_POGnode = SearchQCc, k, j) \neq NULL)\) evaluates to true for event 3:0S1. The values of the variables after this iteration are:
\[ \text{Rec\_wo\_Sends} = \{1\} \]
\[ \text{FoundProcs} = \{0\} \]
\[ \text{Sends} = \{0\} \]
\[ i = 1 \]
\[ \text{RwoSQ} = (<2.1.2, 2:1R2>) \]
\[ \text{SendQ} = (<3.0.3:0S1>) \]
\[ \text{RecvQ} = (<3.1.3:1R0>) \]
\[ \text{POGnode} = 1:0S1, 2:2S1 \]

For the third iteration of the loop, the if statement \((k \in \text{Rec\_wo\_Sends} \text{ AND } (\text{Recv\_POGnode} = \text{SearchQ}(c, k, j)) \neq \text{NULL})\) evaluates to true for event 2:2S1. The values of the variables after this iteration are:

\[ \text{Rec\_wo\_Sends} = \emptyset \]
\[ \text{FoundProcs} = \{0, 2\} \]
\[ \text{Sends} = \{0, 2\} \]
\[ i = 1 \]
\[ \text{RwoSQ} = \text{NULL} \]
\[ \text{SendQ} = (<3.0.3:0S1>, <2.2.2:2S1>) \]
\[ \text{RecvQ} = (<3.1.3:1R0>, <2.2.2:1R2>) \]
\[ \text{POGnode} = \text{root} \]

The condition of the while loop evaluates to false, and the \(LCP\) and \(LCP'\) events for \(PO_1\) are identified in \(\text{SendQ}\) and \(\text{RecvQ}\). The \(LCP\) events are 3:0S1 and 2:2S1, and the \(LCP'\) events are 3:1R0 and 2:1R2. For \(PO_2\), algorithm \text{FindLCPs()} identifies the \(LCP\) events 3:0S1 and 2:2S1, and the \(LCP'\) events 3:1R0 and 2:1R2. These events are underlined in figure 6.17. In this particular example, the \(LCP\) and \(LCP'\) events are the same for both partial orders, but this is not always the case. Notice that the send and receive of the first
message from \( P_0 \) to \( P_1 \) are not identified as \( LCP \) and \( LCP' \) events. This message need not be used for piggybacking data.

The properties resulting from this algorithm are:

1. Event \( e_j \) is an \( LCP \) event if and only if event \( e_j \) is an entry in \( SendQ \).
2. Event \( e_j \) is an \( LCP' \) event if and only if event \( e_j \) is an entry in \(RecvQ \).

These two properties establish that our technique for identifying \( LCP \) and \( LCP' \) events is valid. Two lemmas are prerequisites for proving these properties.

**Lemma 6.4** If \( \text{Find\_LCPs()} \) adds send event \( e_k \) to \( SendQ \), \( e_k \) is an event of a non-repetitive communication path, and \( e_k \) is an \( LCP \) event.

**Proof.**

Event \( e_i \) is the assert event of \( P_i \).

**Basis.**

If \( e_k = c:kSi \), \( k \in \text{Rec\_wo\_Send} \) and \( \text{RwoSQ} \) has the entry \( <c, i, k, POG\_node> \), then

\( c:kSi \) is an event of the non-repetitive communication path \( c:kSi \rightarrow c:iRk \) and \( e_k \) is an \( LCP \) event.

**Proof:** By definition 5.2, \( c:kSi \rightarrow c:iRk \) is a non-repetitive communication path. The send event \( c:kSi \) is the \( LCP \) event of \( P_k \) if \( c:kSi \rightarrow c:iRk \) and there does not exist another send event \( e'_k \) such that \( c:kSi \rightarrow e'_k \rightarrow c:iRk \rightarrow e_i \). Since \( c:kSi \) is the corresponding send to \( c:iRk \) (\( \text{RwoSQ} \) has the entry \( <c, i, k, POG\_node> \) then \( c:kSi \rightarrow c:iRk \rightarrow e_i \), and since \( k \in \text{Rec\_wo\_Send} \), \( e'_k \) does not exist.
**Inductive Hypothesis.**

The events $jR_k, jS_l, lR_j, \ldots mS_i, iR_m$ form a non-repetitive communication path of length $n$, and $iR_m \rightarrow e_i$.

**Inductive Step.**

If $e_k = c:kS_j$, then

1. the send event $c:kS_j$ is added to the non-repetitive communication path $jR_k, jS_l, lR_j, \ldots mS_i, iR_m$ to form the non-repetitive communication path $kS_j, jR_k, jS_l, lR_j, \ldots mS_i, iR_m$ of length $n + 1$, and

2. the send event $c:kS_j$ is an $LCP$ event.

**Proof:**

The event $c:kS_j$ is the corresponding send of $c:jR_k$, and the relationship $c:kS_j \rightarrow c:jR_k$ is true. Therefore, $kS_j, jR_k, jS_l, lR_j, \ldots mS_i, iR_m$ is a non-repetitive communication path (definition 5.2) of length $n + 1$. Event $c:kS_j$ is added to $SendQ$ by algorithm $Find\_LCPs()$ when it is found to be part of the non-repetitive communication path.

We know $c:kS_j \rightarrow e_i$ since $c:kS_j$ is an event of $kS_j, jR_k, jS_l, lR_j, \ldots mS_i, iR_m$ and $iR_m \rightarrow e_i$. From the basis and $c:kS_j \rightarrow e_i$, we can conclude that $c:kS_j$ is an $LCP$ event.

**Lemma 6.5** If $Find\_LCPs()$ adds receive event $jR_k$ to $RecvQ$, $jR_k$ is an event of a non-repetitive communication path and $jR_k$ is an $LCP'$ event.
CHAPTER 6. STATIC ANALYSIS

Proof.

For event $j_Rk$ to be added to $RecvQ$, $k$ must first be an entry in $RecwoSends$ and $RwoSQ$ contains the entry for $c:j_Rk$. For these to exist, we know from algorithm $Find\_LCPs()$

- $j \in Sends$ or $j = i$. and
- $k \notin FoundProcs$

Consider the two possibilities:

1. $j \in Sends$ and $k \notin FoundProcs$.

   From lemma 6.4, if $j \in Sends$, a non-repetitive communication path exists from a $LCP$ send of $P_j$, $jSl$. to a $LCP'$ event of $P_i$, $iRm$: $jSl,...,iRm$. And for $k \notin FoundProcs$, the $LCP$ and $LCP'$ of $P_k$ have not been found in the POG. We can also conclude that $j_Rk \rightarrow jSl$. For $j_Rk$ to be added to $RecvQ$, the send $kSj$ must have been found in an ancestor node of the of $j_Rk$ (from algorithm $Find\_LCPs()$).

   Therefore, $kSj \rightarrow j_Rk$. From this we can conclude the send event corresponding to $j_Rk$. $kSj$, is found and is an $LCP$ event (Lemma 6.4). $j_Rk$ is an $LCP'$ event, and $j_Rk$ is an event of the non-repetitive communication path $kSj,j_Rk,jSl,...,iRm$.

2. $j = i$ and $k \notin FoundProcs$. Event $j_Rk$ is a receive event of the process evaluating the assert, and the $LCP$ event of $P_k$ has not been found. Then for $j_Rk$ to be added to $RecvQ$, the send $kSj$ has been found in the POG, is the $LCP$ event of $P_k$ and forms the non-repetitive communication path $kSj,j_Rk$ (lemma 6.4). Since $j_Rk$ is the corresponding receive of $kSj$, $j_Rk$ is an $LCP'$ event.

\[\]

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
**Property 6.14** Event $e_j$ is an LCP event if and only if event $e_j$ is an entry in $SendQ$.

**Proof.**

**PART 1.** If $e_j$ is an LCP event, then $e_j$ is in $SendQ$.

Proof by contradiction.

Assume $e_j = jSk$ is an LCP event but is not in $SendQ$. Since $jSk$ is an LCP event, there exists a non-repetitive communication path $jSk, kRj, kSl, lRk, \ldots, mSi, iRm$ that consists of LCP and $LCP'$ event where $jSk \rightarrow kRj \rightarrow kSl \rightarrow lRk \rightarrow \cdots \rightarrow mSi \rightarrow iRm$ (theorem 5.1 and definition 5.2). For $jSk$ to not be in $SendQ$, $kRj$ is not in $RwoSQ$ and $k$ is not in $Rec\_wo\_Sends$. For this to occur either

1. $j \in FoundProcs$ or
2. $k \notin Sends$.

1. For $j$ to be in $FoundProcs$, another $e_j'$ exists where $e_j'$ is in $SendQ$ and $e_j'$ is an LCP event of $P_j$. But since $P_j$ can have only one LCP event (lemma 4.1) a contradiction has been reached.

2. For $k \notin Sends$, $kSl$, the LCP event of $P_k$, is not in $SendQ$. The same reasoning holds as to why each LCP event of the non-repetitive communication path $jSk, kRj, kSl, lRk, \ldots, mSi, iRm$ is not in $SendQ$ except for $mSi$. For $mSi$ to not be an LCP event, $iRm$ is not recognized as an $LCP'$ event. For $iRm$ to not a $LCP'$ event, $m$ must be in $FoundProcs$. For $m$ to be $FoundProcs$, a send event $e_m$ and a receive event $e_i'$ exist where $mSi \rightarrow iRm \rightarrow e_m \rightarrow e_i'$. Thus $e_m$ is the
LCP event of $P_m$ (definition 4.1). A contradiction has been reached since $mSi$ is the LCP event of $P_m$.

**PART 2.** If $e_j$ is in $SendQ$, then $e_j$ is an LCP event.

Proof. This follows directly from lemma 6.4.

**Property 6.15** Event $e_j$ is an LCP' event if and only if event $e_j$ is an entry in $RecvQ$.

Proof.

**PART 1.** If $e_j$ is an LCP' event, then $e_j$ is in $RecvQ$.

Proof.

If $e_j = jRk$ is a receive LCP' event, then $jRk$ is part of a non-repetitive communication path to an LCP' event of $P_i$ that consists of LCP and LCP' events. $jSk, kRj, kSl, lRk, \ldots mSi, iRm$ (theorem 5.1). We know the LCP sends are entries in $SendQ$ (property 6.14). If the sends are entries in $SendQ$, then the corresponding receives are also entries in $RecvQ$ according to algorithm Find.LCPs().

**PART 2.** If $e_j$ is in $RecvQ$, then $e_j$ is an LCP' event.

Proof. This follows directly from lemma 6.5.
6.5 \textit{POG} and Taylor's Complete Concurrency History

Taylor's work motivated our static analysis to generate the \textit{POG} for representing the possible executions of a distributed system, but our static analysis algorithms have been developed independent of Taylor's work. The only portion of our static analysis that is a derivation of Taylor's static analysis is representing each process with a flow graph and the successor relationship between nodes of the graph.

A path of the \textit{POG} has a different meaning from a path in Taylor's complete concurrency history. A path of Taylor's history represents a possible total ordering of i/o rendezvous and does not represent the concurrent execution of i/o rendezvous. Each path of the \textit{POG} represents a partial order of the distributed system, and a path does represent the concurrency of the communication commands. One or more of Taylor's paths can correspond to one path of the \textit{POG} since one or more total orders can correspond to the same partial order.

6.6 Static Analysis in the Parallel Domain

Work in the parallel domain that is most closely related to ours is the automated parallelization of sequential code. Parallelizing compilers collect data flow information for a source program and use this information to detect potential parallelism, determine an appropriate grain size, and then transform the program into a functionally equivalent parallel program that can exploit the underlying architecture. These compilers also aim at automating the selection of data distributions and reducing nonlocal data accesses in distributed memory.
The majority of the data flow analysis performed by these compilers is dependence analysis. Two computations that have a dependence relationship means that constraints on their execution order are present. By identifying these constraints with dependence analysis, it can be determined whether transformations of the source code will alter the semantics of the computation.

Two types of dependencies that can be identified with data flow analysis are data and control. Consider two statements, \(a\) and \(b\), of a sequential program. Statement \(b\) is control dependent on statement \(a\) if \(a\) determines whether \(b\) executes. Statements \(a\) and \(b\) have a data dependence if they cannot be executed simultaneously because of conflicting uses of the same variable.

Dependence analysis performed at the procedure and function level is useful for identifying coarse grain parallel transformations [35, 17, 24, 23, 36]. Dependence analysis performed at the loop level is useful for identifying fine grain parallelism [6, 10, 11, 9, 25, 36]. Languages, such as Fortran D [34], provide commands the programmer uses to annotate the sequential program with data decompositions. The compiler then performs dependence analysis to determine the computation decomposition [2]. Other languages [32, 2] exist in which the compiler determines both data and computation decompositions with the aid of dependence analysis.

The objective of the compiler is to produce parallel code in which the execution is maximally parallel and nonlocal data accesses are minimized. Dependency analysis provides information for achieving this objective.
Initially our static analysis appeared similar to the static analysis performed by parallelizing compilers. By comparing the two more closely, the similarities are only superficial. A parallelizing compiler generates control flow graphs of the sequential program and performs sequential data flow analysis. The compiler uses these results to create a functionally equivalent parallel program and decompose the sequential program's data. As part of this process, the necessary communication commands are also created. Our work generates control flow graphs for the source code of the distributed processes to analyze the communication. The source code is already comprised of communication commands. We do not perform dependence analysis and we do not add communication to the distributed system.

In the next chapter, the analysis of distributed programs with the addition of loops is described. The distributed programs in chapter 2 are analyzed in chapter 8, and the \textit{LCP} and \textit{LCP}' events determined. These programs further demonstrate the benefits of identifying \textit{LCP} and \textit{LCP}' events for reducing the number of messages that piggyback data.
Chapter 7

Loops

Chapter 6 presented algorithms for creating the $FG_i$, $H$ and $POG$ graphs. Algorithms where also presented for determining the $LCP$ and $LCP'$ events of an assert statement from the $POG$. These algorithms did not support loops in the source code of the distributed processes. In this chapter we make the additions to the algorithms to allow loops. and the algorithms are modified so all properties and lemmas of chapter 6 are preserved. By concluding with the preservation of properties 6.14 and 6.15. we demonstrate that our technique remains valid for identifying $LCP$ and $LCP'$ events.

7.1 Control Flow Graphs

Three loops constructs can occur in the source code of a process: do - while. while, and for. Each loop has one unique entry point and one unique exit point. Nesting of loops are allowed, but each loop has its own entry and exit point. Neither goto nor break statements are allowed in the source code since either can create additional entry or exit points for loops.
Algorithm Create\_FG\_i() requires additions for representing loops in FG\_i. Each loop in a process’s source code is represented as a cycle in the process’s corresponding flow graph. The cycle is accomplished with a back edge from the exit point of the loop to the entry point of the loop. The concept of a dominating node is necessary to define a back edge. A node \( a \) of flow graph \( FG_i \) dominates node \( b \) of \( FG_i \) if every path from the root node of \( FG_i \) to node \( b \) passes though \( a \). If \((a, b)\) is an edge, then \( a \) is the initial node and \( b \) is the terminal node. An edge is a back edge if its terminal node dominates its initial node. An edge of a flow graph that is not a back edge is referred to as either a forward edge or an edge.

The control flow graph for a process, \( FG_i \), requires additional node types for representing loops. The entry point of a loop is represented with a head node, and the exit point of a loop is represented with a tail node. The head and tail of a while loop are nodes labeled WHILE and END\_WHILE, respectively. The head and tail of a do - while loop are nodes labeled DO and END\_DO, respectively. The head and tail of a for loop are nodes labeled FOR and END\_FOR, respectively. The nodes that occur between the head and tail nodes make up the body of the loop.

The while and for loop are similar in that the loop condition is evaluated at the head of the loop. The loop body is executed zero or more times. This type of loop is referred to as a precondition loop. The loop condition of the do loop is evaluated at the tail of the loop so the loop body is executed one time before testing the condition. This type of loop is referred to as a postcondition loop.

Algorithms Create\_FG\_i() and AddNode() are repeated from chapter 6 with the additions required for the loop constructs. Figure 7.1 shows the three loop constructs represented.
by a portion of a control flow graph. The dashed edges between nodes indicate the edges added by algorithm AddNode() when NewNode is added to the flow graph. A back edge is added by Create FG_i() for any one of the loop constructs from the tail of the loop (e.g., END WHILE node) to the head of the loop (e.g., WHILE node). The back edge creates a cycle in the graph.

Three additional stacks and three additional variables are required to handle loops in algorithm Create FG_i(). The stacks are WhileStack, DoStack and ForStack. The three pointer variables are TopDoStack, TopWhileStack, and TopForStack. Each pointer references the top entry of its respective stack. The stacks are initially empty, and the pointers are initially NULL. The stacks are used to match the begin and end of the loop constructs.

Create FG_i() /* Input: P_i; Output: FG_i */

Create the ROOT node of FG_i
CrtNode = ROOT node
if an assignment statement is recognized
    Add assignment statement to the tail of the linked list
if an async_send is recognized
    if the linked list is not empty
        AddNode(CrtNode, ASSIGN)
        linked list is set to empty
    AddNode(CrtNode, SEND)
if an async_recv is recognized
    if the linked list is not empty
        AddNode(CrtNode, ASSIGN)
        linked list is set to empty
    AddNode(CrtNode, RECEIVE)
if an assert is recognized
    if the linked list is not empty
        AddNode(CrtNode, ASSIGN)
        linked list is set to empty
    AddNode(CrtNode, ASSERT)
if an if statement is recognized
    if the linked list is not empty
        AddNode(CrtNode, ASSIGN)
        linked list is set to empty
    AddNode(CrtNode, ASSERT)
AddNode(CrtNode, ASSIGN) /* for the assignment statements */
linked list is set to empty
AddNode(CrtNode, IF) /* for the if statement */
Push CrtNode onto the stack
TopStack = CrtNode
if an else is recognized
AddNode(CrtNode, END_IFSIDE)
if the linked list is not empty
Set field in CrtNode to point to linked list
linked list is set to empty
TopStack.HoldPtr = CrtNode /* Set HoldPtr of the IF node to the */
/* address of the END_IFSIDE */
CrtNode = top entry of the stack
CrtNode.AddEdgeFlag = true /* Flag an edge needed from END_IFSIDE node */
/* to the first node following END_ELSE node */
if the end of the else side of an if/else is recognized
AddNode(CrtNode, END_ELSE) /* for the ending of the else side */
if the linked list is not empty
Set field in CrtNode to point to linked list
linked list is set to empty
CrtNode.HoldPtr = TopStack.HoldPtr /* Move the address of the END_IFSIDE */
/* node to the END_ELSE node */
CrtNode.AddEdgeFlag = true /* Flag an edge will be needed from END_IFSIDE */
/* node to the first node following END_ELSE node */
Pop the stack
if the end of an if statement is recognized
AddNode(CrtNode, END_IF) /* for the ending of the if statement */
if the linked list is not empty
Set field in CrtNode to point to linked list
linked list is set to empty
CrtNode.HoldPtr = TopStack /* Set the HoldPtr of END_IF node */
/* to the address of the IF node */
CrtNode.AddEdgeFlag = true /* Flag an edge will be needed from the IF node */
/* to the first node following the END_IF node */
Pop the stack
if a while statement is recognized
if the linked list is not empty
AddNode(CrtNode, ASSIGN) /* for the assignment statements */
linked list is set to empty
AddNode(CrtNode, WHILE) /* for the if statement */
Push CrtNode onto WhileStack
TopWhileStack = CrtNode
if a for statement is recognized
if the linked list is not empty
AddNode(CrtNode, ASSIGN) /* for the assignment statements */

linked list is set to empty
AddNode( CrtNode, FOR) /* for the if statement */
Push CrtNode onto ForStack
TopForStack = CrtNode
if a do statement is recognized
if the linked list is not empty
AddNode( CrtNode, ASSIGN) /* for the assignment statements */
linked list is set to empty
AddNode( CrtNode, DO) /* for the if statement */
Push CrtNode onto DoStack
TopDoStack = CrtNode
if the end of a while loop is recognized
AddNode( CrtNode, END.WHILE) /* for the end of the while loop */
if the linked list is not empty
Set field in CrtNode to point to linked list
linked list is set to empty
Add back pointer from CrtNode to TopWhileStack /* create cycle in the graph */
CrtNode.HoldPtr = TopWhileStack /* Set the HoldPtr of END.WHILE node */
/* to the address of the WHILE node */
CrtNode.AddEdgeFlag = true /* Indicate an edge will be needed from the WHILE */
/* node to the first node following the END.WHILE node */
Pop WhileStack
if the end of a for loop is recognized
AddNode( CrtNode, END.FOR) /* for the end of the for loop */
if the linked list is not empty
Set field in CrtNode to point to linked list
linked list is set to empty
Add back pointer from CrtNode to TopForStack /* create cycle in the graph */
CrtNode.HoldPtr = TopForStack /* Set the HoldPtr of END.FOR node */
/* to the address of the FOR node */
CrtNode.AddEdgeFlag = true /* Indicate an edge will be needed from the FOR */
/* node to the first node following the END.FOR node */
Pop ForStack
if the end of a do loop is recognized
AddNode( CrtNode, END.DO) /* for the end of the do loop */
if the linked list is not empty
Set field in CrtNode to point to linked list
linked list is set to empty
/* create cycle in the graph for loop */
Add back pointer from CrtNode to node reference by TopDoStack
Pop DoStack
if the current control construct or statement is not recognized
Generate an error and halt
if the end of the source code is recognized
AddNode( CrtNode, END)
If the linked list is not empty
Set field in $CrtNode$ to point to linked list
linked list is set to empty
end algorithm

The only valid exit point of a postcondition loop is from the tail of the loop. Algorithm $AddNode()$ creates an edge from the END.DO node to the first node added to the graph after the END.DO node ($NewNode$). The only valid exit point of a precondition loop is from the head of the loop. Algorithm $AddNode()$ creates an edge from the WHILE node and the FOR node to the first node that occurs after the loop's end node.

$$AddNode(CrtNode, type)$$
$$NewNode = Allocate a node$$
$$if CrtNode ≠ END.WHILE. END.FOR$$
$$Create a directed edge from CrtNode to NewNode$$
$$if CrtNode.AddEdgeFlag$$
$$Create a directed edge from the node CrtNode.HoldPtr to NewNode$$
$$if type = ASSIGN$$
$$Set field in NewNode to point to assignment linked list$$
$$CrtNode = NewNode$$
end algorithm

Algorithm $AddNode()$ does not require additional code or modification to create the edge from the exit point of a do-while loop. Additional code is required for the exit point of the while and for loops. To create an edge from a WHILE or FOR node to $NewNode$, the same steps are taken when an edge is added from an IF node to the END_IF node. The description of this process is presented in terms of the while loop, but is generalized to any precondition loop. When the END.WHILE node is added, the address of the WHILE node, available on top of $WhileStack$, is stored in the END.WHILE node. This is accomplished with the following line from $Create_FG()$: 

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
CHAPTER 7. LOOPS

130

\[ \text{Figure 7.1: Control flow graph of the loop constructs} \]

\[ CrtNode.HoldPtr = TopWhileStack \]

When \( NewNode \) is added to \( FG \), the address of the WHILE node is available in \( CrtNode \) so that \( \text{AddNode()} \) can create an edge from the WHILE node to \( NewNode \). The flag \( \text{AddEdgeFlag} \) of the END_WHERE node is set to \text{true} \ to indicate that function \( \text{AddNode()} \) should add an edge from the WHILE node to \( NewNode \).

Properties 6.1 through 6.4 correspond to the control flow graphs. Properties 6.2 and 6.4 are not affected by loops, but property 6.1 requires some modification when loops occur in the source code.

First we will consider precondition loops. Consider the \texttt{while} loop shown in figure 7.2.

If the loop is executed zero times, the happens before relationship among the nodes is:
WHILE → S2

If the loop is executed one time, the happens before relationships among the nodes are:

WHILE → S1 → END_WHILE → WHILE → S2

A new iteration of the loop is begun when the first node of the loop body is executed. In this example, node S1 is the first node of the loop body. The last node of an iteration is the WHILE node. If \( i \) iterations of a precondition loop occur, the WHILE node is executed \( i + 1 \) times, and the back edge is followed \( i \) times. Consider the case when the loop is executed two times. The happens before relationships are:

WHILE → S1 → END_WHILE → WHILE → S1 → END_WHILE → WHILE → S2

The following summarizes the happens before relationships and the beginning and ending of loop iterations for the while loop.

\[
\begin{align*}
\text{WHILE} & \rightarrow \text{S2} \\
\text{WHILE} & \rightarrow \text{S1} \rightarrow \text{END_WHILE} \rightarrow \text{WHILE} \rightarrow \text{S2} \\
& \quad \text{iteration 1} \\
\text{WHILE} & \rightarrow \text{S1} \rightarrow \text{END_WHILE} \rightarrow \text{WHILE} \rightarrow \text{S1} \rightarrow \text{END_WHILE} \rightarrow \text{WHILE} \rightarrow \text{S2} \\
& \quad \text{iteration 1} \quad \text{iteration 2} \\
\text{DO} & \rightarrow \text{S1} \rightarrow \text{END_DO} \rightarrow \text{S2} \\
& \quad \text{iteration 1} \\
\text{DO} & \rightarrow \text{S1} \rightarrow \text{END_DO} \rightarrow \text{DO} \rightarrow \text{S1} \rightarrow \text{END_DO} \rightarrow \text{S2} \\
& \quad \text{iteration 1} \quad \text{iteration 2}
\end{align*}
\]
The happens before relationship and the beginning and ending of loop iterations are also shown for do-\texttt{while} loops, which will be discussed next.

![Control flow graph with a while loop](image)

\textbf{Figure 7.2:} Control flow graph with a while loop

According to property 6.1, if a path exists from node \(a\) to node \(b\), then \(a \rightarrow b\) when both are executed. By examining the happens before relationship between the S1 node and the \texttt{END\_WHILE} node, we see that property 6.1 requires updating. A path exists from node \texttt{END\_WHILE} to node S1 in figure 7.2, but it is not the case that \texttt{END\_WHILE} \(\rightarrow\) S1 when one iteration of the loop occurs. Consider two iterations of the loop. The \texttt{END\_WHILE} of the first iteration does not happen before the S1 of the first iteration, but the \texttt{END\_WHILE} of the first iteration does happen before the S1 of the second iteration. In general, \texttt{END\_WHILE} \(\rightarrow\) S1 if

1. the loop is executed 2 or more times
2. END.WHILE occurs in iteration $i$ of the loop, and

3. $S_1$ occurs in iteration $i + 1$ or greater.

Next we need to examine the postcondition loop. Figure 7.3 shows a flow graph for a do loop. If the loop is executed only one time, the happens before relationships among the nodes are:

$$DO \rightarrow S_1 \rightarrow END.DO \rightarrow S_2.$$  

The happens before relationships for two executions of the loop are:

$$DO \rightarrow S_1 \rightarrow END.DO \rightarrow DO \rightarrow S_1 \rightarrow END.DO \rightarrow S_2.$$  

The boundary nodes of an iteration for a postcondition loop are different than those of a precondition loop. The first execution of DO begins iteration 1 of the loop, and END.DO
completes that iteration. If the loop is iterated \(i\) times, \DO{} and \END\_DO{} are executed \(i\) times, and the back edge is followed \(i - 1\) times.

Consider the happens before relationship between \S{} and \END\_DO{}. A path exists from the \END\_DO{} node to the \S{} node, but the relationship \END\_DO{} \(\rightarrow\) \S{} is true only if

1. the loop is executed more than once,
2. \END\_DO{} occurs in iteration \(i\), and
3. \S{} occurs in an iteration greater than \(i\).

Property 6.1' subsumes property 6.1 to account for the occurrence of loops. The property is given in two parts for completeness, but only part 1 is modified. The variable \(l\) is used to denote a loop.

**Property 6.1'**

**PART 1.** If a path exists from node \(a\) to node \(b\) in \(FG_l\), then \(a \rightarrow b\) when

1. \(a\) and \(b\) are both executed and a back edge is not part of the path from node \(a\) to node \(b\), or

2. \(a\) and \(b\) are both executed, the back edge of loop \(l\) is part of the path from node \(a\) to \(b\), node \(a\) occurs in iteration \(i\) of loop \(l\) and node \(b\) occurs in iteration \(j\), where \(j > i\), of loop \(l\), or

3. \(a\) and \(b\) are both executed, the back edge of loop \(l\) is part of the path from node \(a\) to \(b\). loop \(l\) is a precondition loop. nodes \(a\) and \(b\) occur in the same iteration, and node \(b\) is the head of the loop.
PART 2. If \( a \rightarrow b \) when both \( a \) and \( b \) are executed, then a path exists from node \( a \) to node \( b \) in \( FG_i \).

Condition (1) of part 1 is equivalent to property 6.1. Conditions (2) and (3) quantify which happen before relationships are possible with the addition of back edges. Condition (2) of part 1 allows the relationship END\_WHILE \( \rightarrow \) S1 of figure 7.2 when multiple iterations of the loop occur, and S1 occurs in a later iteration than END\_WHILE. Also notice that this condition allows the happens before relationship WHILE \( \rightarrow \) WHILE where the first WHILE occurs in an earlier iteration than the second. As for postcondition loops, the condition S1 \( \rightarrow \) DO is allowed for figure 7.3 when two or more iterations occur. Condition (3) of part 1 allows S1 \( \rightarrow \) WHILE when both occur in the same iteration.

7.2 \( H \) Graph

With the possibility of loops in the source code of each process of the distributed system, loops are also possible in \( H \). In the algorithm for constructing \( H \), additions are required for detecting the repeated execution of communication commands and representing these repetitions as cycles in \( H \). Cycles occur in \( H \) if

1. a send command is in the body of a loop and the send is possible.

2. a send command is possible, the matching receive is ready, and both occur in the body of a loop. or

3. a combination of (1) and (2).
Cycles are created in $H$ with back edges. The graph retains the properties of a tree; there exist a root node and leaf nodes. The terminology ancestor, descendant, parent and child will remain in use for the relationships defined by forward edges. The relationships between nodes defined by back edges will be discussed following the modified Crt.H() algorithm.

Properties 6.5 through 6.8 and lemma 6.1 correspond to the $H$ graph. The substantial changes to the $H$ graph construction algorithm do not invalidate these properties and lemma. The node relationship ancestor is fundamental to properties 6.5 and 6.7, and these properties remain valid with the clarification of the ancestor relationship. Properties 6.6 and lemma 6.1 are not affected by loops. Property 6.8 is discussed following the modified Crt.H() algorithm.

Figure 7.4: Example 1

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
The detection of loops in $H$ requires significant additions to the $\text{Crt}_H()$ algorithm. Two examples, useful for describing the additions to $\text{Crt}_H()$, demonstrate the occurrence of loops in $H$. The first example is a two process distributed system. The source code of each process and the graph resulting from algorithm $\text{Crt}_H()$ in chapter 6 is shown in figure 7.4. The graph $H$ can not accurately represent the execution of this distributed system without back edges. Communication commands are repeatedly executed, but the loops are not shown as cycles in $H$ since this version of the algorithm does not detect loops. A pattern can be observed in $H$. The nodes $(2:\text{async\_send}(1), 1:\text{async\_recv}(0))$ and $(3:\text{async\_send}(1), 2:\text{async\_recv}(0))$ of figure 7.4 represent the same state of the system. Although the counters corresponding to the sends and receives differ, the send in each node represents the same command in $P_0$, and the receive in each node represents the same command in $P_1$. Another system state is represented by nodes $(3:\text{async\_send}(1), \_\_\_\_\_\_)$ and $(4:\text{async\_send}(1), \_\_\_\_\_\_\_\_\_\_\_\_\_\_)$. The complete $H$ graph with the inclusion of back edges is shown in figure 7.5.
CHAPTER 7. LOOPS

![Diagram of Example 2]

Figure 7.6: Example 2

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
Loop detection is more difficult in the example of figure 7.6. The nodes (2: async_send(1), 1: async_recv(0)) and (3: async_send(1), 2: async_recv(0)) syntactically appear to represent the same state, but they do not. The node (2: async_send(1), 1: async_recv(0)) represents the first send of $P_0$ and the first receive of $P_1$, whereas the node (3: async_send(1), 2: async_recv(0)) represents the second send in $P_0$ and the second receive in $P_1$. Nodes
(2:async_send(1), 1:async_recv(0)) and (4:async_send(1), 3:async_recv(0)) represent the same state of the system, and nodes (3:async_send(1), 2:async_recv(0)) and (5:async_send(1), 4: async_recv(0)) represent another state of the system. The complete $H$ graph representing the execution of the distributed system with back edges is given in figure 7.7.

Additional information is required to detect and represent loops in $H$. For each node, $n$, of $H$ the following information is needed.

- A temporary back edge, temp.back, used by Crt.H() is a field of $n$.

- An array of node pointers that are the children of $n$. Kids[MAXEDGES] is a field of $n$. Each entry represents a child that is the result of a forward or back edge. The forward edge children occur first in the array.

- An array of integers Kid.type[MAXEDGES], where Kid.type[i] indicates the type of edge for Kids[i], is a field of $n$. A zero entry indicates a forward edge, and a one entry indicates a back edge.

- An array of pointers to the parents nodes of $n$. Parents[2], is a field of $n$. Entry Parents[0] is the parent of $n$ that is defined by a forward edge. Each node has a parent from a forward edge. If a node is pointed to by a back edge, then the node also has a parent that is defined by a back edge. The entry Parent[1] is the parent of $n$ that is defined by a back edge or NULL if the $n$ is not pointed to by a back edge. An example of a parent resulting from a back edge is node (3:async_send(1), 2:async_recv(0)) which is a parent of (2:async_send(1), 1:async_recv(0)) of figure 7.7.
When node $n$ is added to $H$, a check is made to determine if the state represented by this node has already been represented by another node in $n$'s execution path. This is done by comparing $n$ with its ancestors. First $n$ is compared with its parent. If the parent does not represent the same state, then the grandparent is compared against $n$. This continues until either a node that represents the same state of $n$ is found or the root node is reached.

Two comparisons are required to determine if node $n$ and its ancestor node, $n'$, represent the same state. The first comparison identifies *syntactically* identical nodes. *Syntactically* identical meaning that for each entry, $v_i$, in $n$, there exists $v'_i$ in $n'$ which is identical with the exception of the counter value. If nodes $n$ and $n'$ are syntactically identical, the second comparison is necessary to determine whether the nodes represent the same state. For each pair of entries, $v_i$ and $v'_i$, where $v_i$ and $v'_i$ are not equal to the inactive marker, the test insures that $FGnode[i]$ of $n$ is equal to $FGnode[i]$ of $n'$. If $FGnode[i]$ of $n$ is equal to $FGnode[i]$ of $n'$, both point to the same node of $FG_i$. Passing the test implies that $v_i$ and $v'_i$ represent the same command of $P_i$. If the test is true for each pair, $(v_i, v'_i)$, then the two nodes represent the same state.

If the ancestor node $n'$ represents the same state as node $n$, then $n'$ is possibly the entry point of a loop, and the parent of $n$ is possibly the exit point of this loop. The next decision is whether to add a back edge from the parent of $n$ to $n'$ to form the loop. Two cases exist for the relative location of nodes $n$ and $n'$ in $H$.

1. The parent of node $n$ is also node $n'$.

2. The parent of node $n$ is not node $n'$. Node $n'$ is an ancestor of the parent of node $n$. 

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
CHAPTER 7. LOOPS

If case 1 is true then a loop has been detected in $H$. A back edge is added from $n'$ to itself, and node $n$ is removed from $H$. Figure 7.8, the portion of figure 7.4 needed to demonstrate case 1, shows the transformation of $H$ when the loop is detected. Case 2 requires more information to determine whether a loop has been found in $H$. Figure 7.9 is a distributed system that demonstrates case 2. Nodes $n'$ and $n$ represent the same state, but adding a back edge from the parent of $n$ to $n'$ would be incorrect. The state represented by node $(5:\text{async\_send}(1), 2:\text{async\_recv}(2), -)$ does not recur after node $n$. Additionally, the state represented by nodes $n$ and $n'$ does not recur after node $n$.

Continuing to generate nodes of the execution path that includes $n$ and $n'$ is necessary to determine if a loop exists in $H$. If the nodes from $n'$ to the parent of $n$ are duplicated immediately after $n$, a loop exists in $H$. A back edge is added from the parent of $n$ to $n'$ creating a cycle. Node $n$ and its descendants are removed from $H$.

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
The algorithm Check_Loops() checks for cases 1 and 2. Determining whether a back edge should be added for case 2 requires the use of field temp.back. Whenever case 2 is true, Check_Loops() sets the field temp.back of n's parent to point to n'. Figures 7.10 and 7.11 demonstrate the use of temp.back. The dashed edge represents the value of temp.back. Figures 7.10 and 7.11 show the generation of H in figure 7.6 as each node is added. Only the portion of H relevant to the addition of a back edge is shown.

Step 3 of figure 7.10 shows the first occurrence case 2. Nodes n and n' represent the same state and a temporary back edge (temp.back) is added from the parent of n to n'. A back edge can not be added until it is known that the state represented by node (3:async_send(1). 2:async_recv(0)) occurs again immediately after node n. The node added in step 4. (5:async_send(1). 4:async_recv(0)) represents the same state as node (3:async_send(1). 2:async_recv(0)). A temporary back edge is added from the parent of n (4:async_send(1). 3:async_recv(0)) to n' (3:async_send(1). 2:async_recv(0)). When this temporary back edge is added, n' also has a temporary back edge that points to node (2:async_send(1). 1:async_recv(0)). This indicates that the state of nodes (2:async_send(1). 1:async_recv(0)) and (3:async_send(1). 2:async_recv(0)) are repeated by (4:async_send(1), 3:async_recv(0)) and (5:async_send(1), 4:async_recv(0)) nodes. The temporary back edge of node n' becomes the back edge, and the nodes after n' are removed as shown in the resulting H.

Figure 7.11: Detecting a loop

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
When node $n$ is added to $H$, algorithm Crt_H() invokes algorithm Check_Loops() to check for the existence of a loop with the additional node. Algorithm Check_Loops() checks the ancestors of $n$ for a node representing the same state as $n$. If one is found, the variable Poss.Head is set to the matching node, and variable Poss.Tail is set to the parent of $n$. If Poss.Head and Poss.Tail refer to the same node, an occurrence of case 1 is found, a back edge is added from Poss.Head to itself, and node $n$ is removed from $H$. If case 2 is verified, nodes from the parent of Poss.Tail to Poss.Head are traversed checking for values in temp.back. If all nodes have values in temp.back, then the loop has been repeated. In Poss.Head, the value of temp.back is replicated as the back edge. If any node has no value in temp.back, the potential loop body has not been repeated.

When a loop is added to $H$, nodes require removal. If a back edge is added for case 1, then only node $n$ needs to be removed. When a back edge is added for case 2, the nodes and their children that were created to duplicate the loop body must be removed. When traversing $H$ from the parent of Poss.Tail to Poss.Head, the variable prev.traverse is set to the previously checked node. If a back edge is added, node prev.traverse and its children are removed by the Remove_NODES() function. Entries may remain in CCS.Q for children of the removed node. When a node is removed from $H$, the queue CCS.Q is scanned for entries whose parent is the removed node. If any are found, they are removed from CCS.Q by the RemoveQ() function.

The addition of back edges to $H$ represents the repeated execution of a portion of the distributed system's execution. When following a possible execution path of $H$ and a back edge occurs in the path, this back edge represents an iteration of the loop associated with the back edge. If, when considering only the forward edges of $H$.

- nodes $a$ and $b$ are in an execution path in $H$.
- nodes $a$ and $b$ are both nodes of the same loop, and
- node $a$ is an ancestor of node $b$.

then, when considering forward and back edges.

- $b$ is an ancestor of $a$ when $b$ occurs in iteration $i$ of the loop and $a$ occurs in an iteration greater than $i$, and
- $a$ is an ancestor of $b$ when $a$ occurs in iteration $i$ and $b$ occurs in iteration $i$ or greater.
Referring back to figure 7.7, node (2:async_send(1), 1:async_recv(0)) is an ancestor of node (3:async_send(1), 2:async_recv(0)), and node (3:async_send(1), 2:async_recv(0)) is an ancestor of (2:async_send(1), 1:async_recv(0)). The first ancestor relationship is inherent, but the second is only possible with the addition of the back edge. The second relationship is true only when node (3:async_send(1), 2:async_recv(0)) occurs in iteration \(i\) and node (2:async_send(1), 1:async_recv(0)) occurs in an iteration greater than \(i\).

If node \(a\) is an ancestor of node \(b\), then \(b\) is a descendant of \(a\). The children of \(a\) are the descendants of \(a\) whose path length from \(a\) is equal to one. This path can be a forward or back edge. If \(b\) is a child of \(a\), then \(a\) is the parent of \(b\).

Property 6.8 states that tree \(H\) represents all the partial orders of the distributed system. Without back edges in \(H\), the number of partial orders is finite. If \(H\) has back edges, the partial orders are known but the number of partial orders is potentially infinite. A bound is not known for the number of times a loop can be iterated. Each path from the root to a leaf node that includes a back edge represents a group of partial orders that have a repeating pattern. Graph \(H\) continues to represent all the partial orders.

### 7.3 POG

In chapter 6, the input to the algorithm Crt_POG() is the tree \(H\) and the output is the POG. With the possibility of back edges in \(H\), the POG can also have back edges. Only the function EQUIV() of algorithm Crt_POG() is affected by the addition of back edges in \(H\). Properties 6.9 through 6.13 and Lemmas 6.2 and 6.3 correspond to the POG. We
demonstrate that these properties and lemmas are maintained with the addition of back edges.

Function \texttt{EQUIV()} serves the same function as described in chapter 6. However, the inclusion of back edges requires additional tests to determine equivalency of $H$ nodes. Suppose $CCS$ and $CCS'$ are found to have equivalent communication commands, and the nodes that represent $CCS$ and $CCS'$ are $n$ and $n'$. Function \texttt{EQUIV()} must check whether

1. $n$ or $n'$ is pointed to by a back edge, or
2. $n$ or $n'$ has a back edge.

Function \texttt{EQUIV()} calls function \texttt{Check-Back()} to determine if either (1) or (2) are true. If neither (1) nor (2) occurs, $n$ and $n'$ are equivalent. Both cases require further tests to determine equivalence.

In case (1), if only one of the nodes is referenced by a back edge, then $n$ and $n'$ are not equivalent. When nodes $n$ and $n'$ are each pointed to by a back edge, both node $n$ are entry points of loops in $H$. The next test determines whether the loop associated with node $n$ is equivalent to the loop associated with node $n'$. The recursive function \texttt{TreeCmp()} of algorithm \texttt{Crt-POG()} determines the equivalence of the two loops.

Node \texttt{back} is the node that has a back edge to node $n$, and node \texttt{back'} is the node that has a back edge to node $n'$. Nodes $n$ and \texttt{back} define a subtree. Node $n$ is the root node, and the nodes that are descendants of $n$ but not the descendants of \texttt{back} comprise the nodes of the subtree. The variable \texttt{subtree} is the subtree defined by nodes $n$ and \texttt{back}. Nodes $n'$ and \texttt{back'} also define a subtree. \texttt{subtree'}. The two subtrees are traversed in lock step, starting at
the root node, in depth first order. The current node of subtree, \( c \), is compared against the current node of subtree, \( d \). If

1. the CCS of node \( c \) is equivalent to the CCS of node \( d \), and

2. the number of children of \( c \) is equal to the number of children of \( d \),

then the traversal of the subtree continues. If either condition is false, the loops are not equivalent and the traversal stops. If both subtrees are completely traversed without falsifying either condition, then the loops are equivalent. If the loops are equivalent, then nodes \( n \) and \( n' \) are represented by a single node in the POG. The nodes of the equivalent loops, that are not the entry and exit points of the loop, will be united by the original EQUIV() algorithm.

If case 2 is found to be true, then the following two tests are required to determine the equivalence of \( n \) and \( n' \):

1. both \( n \) and \( n' \) have a back edge, and

2. the \( H \) node pointed to by the back edge of \( n \) is equivalent to the \( H \) node pointed to by the back edge of \( n' \).

Function Check_Node() is called by EQUIV() to determine if these two tests are true. If both tests are passed, both \( n \) and \( n' \) will be represented by a single node in the POG.

The equivalent \( H \) nodes described in test 2 will already be represented by one node of the POG as a result of the previous case. A single back edge will be added from the
A POG node that represents \( n \) and \( n' \) to the POG node representing the equivalent \( H \) nodes pointed to by the back edges of \( n \) and \( n' \).

One additional field is added to the \( H \) nodes to transform \( H \) into the POG. The field \( \text{POGnode} \) is added to point to the POG node representing this \( H \) node. More than one \( H \) node may have the same value of \( \text{POGnode} \) since one POG node represents equivalent \( H \) nodes. The POG nodes also require additional fields that are replicated from the \( H \) nodes:

- \( \text{Kids}[\text{MAXEDGES}] \)
- \( \text{Kid\_type}[\text{MAXEDGES}] \)
- \( \text{Parents}[\text{MAXEDGES}] \)

These POG node fields are functionally equivalent to their \( H \) node counterparts. Field \( \text{Kids}[\text{MAXEDGES}] \) is an array of pointers to the children of the POG node. Each entry represents either a forward or back edge. Field \( \text{Kid\_type}[\text{MAXEDGES}] \) is an array of integers indicating the type of edge for each entry. Forward edge have a zero entry, while back edges have a one entry. Pointers to the parents of the POG node are maintained in the array \( \text{Parents}[\text{MAXEDGES}] \).

Algorithm \text{Crt\_POG()} \) and function \text{EQUIV()} \) are shown with required back edge additions. Supportive functions are also shown.

\text{Crt\_POG()}:

Properties 6.9, 6.10, 6.11, and 6.12 are derived directly from the properties of $H$ and are affected by back edges as described in section 7.2. Lemmas 6.2 and 6.3 and property 6.13 remain true with the addition of loops in $H$ and the POG. Modification of algorithm Crt.POG() is limited to additional checks for equivalency of nodes of $H$. The construction of the POG continues to preserve the causal and concurrent relationships in $H$. Property 6.13 states that each path from the root node to a leaf node of the POG represents a unique partial order. If there exists a path from the root node to leaf node $n$ that contains a loop, then a different path exists from the root to $n$ when the nodes of the loop are repeated.

CHAPTER 7. LOOPS

7.4 LCP and LCP' events

The last modifications pertain to the algorithms Bound_Assert() and Find_LCPs() that determine the LCP and LCP' events. Lemmas 6.4 and 6.5 and properties 6.14 and 6.15 correspond to the identification of the LCP and LCP' events. These lemmas and properties are not affected by the possible occurrence of back edges in the POG. Two modifications are required for Bound_Assert(). The first modification stops searching a path for the last LCP' event when the ASSERT node occurs in the body of a loop. Without back edges in flow graph FG, the search stopped when either a RECEIVE node or the root node was encountered. With back edges the search should also stop if the ASSERT node itself is encountered. When Bound_Assert() searches for a RECEIVE node in the flow graph of figure 7.12 two paths are searched. One is the path including only the FOR node and the RECEIVE node. The search stops at the RECEIVE node. The other path starts at the FOR node, proceeds to the END_FOR node by following the back edge. The next node in the path is the ASSERT node. The search terminates since a receive does not exist on the path from the ASSERT node back to itself. If a RECEIVE node exists between the END_FOR node and the ASSERT node, as shown in figure 7.13, the RECEIVE is a last LCP' event and is added to the linked list Local_LCPs. In this case, the search succeeds when the RECEIVE node is encountered.

The second modification is needed when a loop occurs in the path being searched, but the ASSERT node is not part of the loop body. Without modification, the nodes of a loop will be followed infinitely if the loop occurs prior to the ASSERT node and a RECEIVE node is not found. The flow graph in 7.14 demonstrates the problem. The path ASSIGN, FOR,
END_FOR, SEND. FOR, END_FOR, SEND, ... is repeatedly traveled unless a modification is made. When searching a path for a RECEIVE node, each node is flagged as visited when it is encountered. Before following a parent of a node in a search path, the visited flag of that node is tested. If it has not been set, then this path is searched. If it has been previously visited, this path is not searched.

For completeness, we repeat algorithm Bound_Assert() with modifications.

Bound_Assert() /* input: FG, and assert_node */
current_list = the parent nodes of assert_node
NextBranch = NULL
Local_LCPs = NULL
crnt_node = first entry in current_list
Remove crnt_node from current_list
receive_found = false

do
  while (receive_found=false) AND (crnt_node \neq root node of FG) AND (crnt_node \neq assert_node) AND (crnt_node has not been visited))
    if (current_list \neq NULL)
      Push current_list on the stack NextBranch
    endif
    Mark crnt_node as visited
    if crnt_node = receive
      Add crnt_node to Local_LCPs
      receive_found = true
    else
      current_list = parent nodes of crnt_node
      crnt_node = first entry in current_list
      Remove crnt_node from current_list
    endif
  endwhile
if (NextBranch \neq NULL)
  receive_found = false
  current_list = Pop(NextBranch)
  crnt_node = first entry in current_list
  Remove crnt_node from current_list
endif
while (NextBranch \neq NULL)
end algorithm
Algorithm `BoundAssert()` constructs a linked list, `LocalLCPs`, that are the last `LCP` events of the assert. This list is used by algorithm `FindLCPs()` to determine the `LCP` and `LCP'` events of the POG. The search for `LCP` and `LCP'` requires `FindLCPs()` to visit the ancestors of each POG node represented by an `LCP` event in `LocalLCPs`. Changes are necessary to `FindLCPs()` to contend with back edges encountered during the search. Back edges in the POG define additional causal relationships as demonstrated by the portion of the POG shown in 7.15. Without considering the back edge, the causal relationships are
Figure 7.13: Assert and receive in the loop body

1 : 0S1 \rightarrow 1 : 1R0 \rightarrow 1 : 2S0 \rightarrow 1 : 0R2. The causal relationships 1 : 0R2 \rightarrow 1 : 2S0 \rightarrow 1 : 1R0 \rightarrow 1 : 0S1 exist with the back edge. When determining the \( LCP \) and \( LCP' \) events, all casual relationships, including those derived from back edges, must be considered.

A node with a back edge pointing to it has two parents. One parent is the result of a forward edge, and the other parent is the result of a back edge. In the original version of \texttt{Find.LCPs()} , only parent nodes which result from forward edges are searched. To consider all the causal relationships in the \textit{POG}, paths that include parent nodes that are the result of back edges are also searched.
In the POG shown in figure 7.15, the assert occurs in $P_1$, and the receive of node last is the last $LCP$ event of $P_1$. The search for $LCP$ and $LCP'$ events starts at node last. The send of node $n$, $1:0S1$, is found to be an $LCP'$ event. Node $n$ has two parents, one resulting from a forward edge and one resulting from a back edge. At this point the search branches into two paths. The path that includes the parent of node $n$ resulting from a forward edge is searched by the original $\text{Find\_LCPs()}$. The path that includes node $n'$ and node $n''$ should also be searched by $\text{Find\_LCPs()}$ since these nodes are ancestors of node $n$. The receive of node $n''$ is an $LCP$ event and the send of node $n'$ is an $LCP'$ event.
Notice in the POG of figure 7.15 that when the path follows the back edge parent of node \( n \), the path \( \text{last.} n . n'' . n' \) can repeat indefinitely. When a back edge is encountered, the back edge must be followed to consider all causal relationships. By following the back edge once, all additional causal relationships defined by this back edge are considered. Additional variables are required in algorithm \texttt{FindLCPS()} to follow paths that include parent nodes resulting from back edges and to not visit a parent that is the result of a back edge more than once in the same search path. A node is placed in the set \textit{VisitOnce} if the node is a parent node resulting from a back edge, and the node is visited by the current search. Since the search can branch into two different paths, the state of the search prior to the branch is saved. The branch resulting from a forward
edge is visited first. When the search of this branch has been completed, the other branch
is searched by restoring the saved state and continuing the search at the branch point.
An entry in the queue StateQ is the state of a search. The format of an entry in StateQ is
\(<\text{POGNode}, \text{RwoSQ}, \text{SendQ}, \text{RecvQ}, \text{FoundProcs}, \text{Sends}, \text{Rec._wo.Sends}, \text{VisitOnce}>\). The variable POGNode is the parent node resulting from the back edge. The remaining items
are the values of variables before the branch. Algorithm \text{Find.LCPs}() is repeated with the
appropriate modifications.

The changes to algorithm \text{Find_LCPs}() to facilitate searching paths including back edges for \text{LCP} and \text{LCP' events} do not affect lemmas 6.4 and 6.5 and properties 6.14 and 6.15. The entries in \text{SendQ} are the \text{LCP} events, and the entries in \text{RecvQ} are the \text{LCP' events}. No alterations to the method of adding entries into these queues results from the changes.
to \texttt{Find\_LCPs()}. We conclude that our technique for identifying $LCP$ and $LCP'$ events remains valid.

The next chapter analyzes the distributed programs of chapter 2. The resulting \textit{POG} is shown for each program, and the $LCP$ and $LCP'$ are determined from the \textit{POG}.
Chapter 8

Static Analysis of Distributed Programs

We presented five distributed programs in Chapter 2. In this chapter, we apply the algorithms of chapters 6 and 7 to determine the $LCP$ and $LCP'$ events for each distributed program.

8.1 Set Partition

SETPART, the set partition program, is reproduced from section 2.1 with the addition of an assert statement $A_1$ in process $P_1$. 

169
CHAPTER 8. STATIC ANALYSIS OF DISTRIBUTED PROGRAMS

\[ P_0:: \]
\begin{align*}
1 & mx = \max(S) \\
2 & async\_send(1, mx) \\
3 & S = S - \{mx\} \\
4 & async\_recv(1, x) \\
5 & S = S \cup \{x\} \\
6 & mx = \max(S) \\
7 & \text{while}(mx > x) \\
8 & async\_send(1, mx) \\
9 & S = S - \{mx\} \\
10 & async\_recv(1, x) \\
11 & S = S \cup \{x\} \\
12 & mx = \max(S) \\
13 & \text{endwhile}
\end{align*}

\[ P_1:: \]
\begin{align*}
14 & \text{while}(\text{true}) \\
15 & async\_recv(0, y) \\
16 & T = T \cup \{y\} \\
17 & mn = \min(T) \\
18 & async\_send(0, mn) \\
19 & T = T - \{mn\} \\
20 & \text{endwhile}
\end{align*}

An assert statement in either process is adequate for expressing expected system execution behavior. Placing the causal assert statement \( A_1 \) between lines 17 and 18 is useful for detecting incorrect execution and for locating errors in both \( P_0 \) and \( P_1 \). Assert statement \( A_1 \) is evaluated on each exchange.

A false evaluation of \( A_1 \) indicates erroneous execution of the program. SETPART’s error is identified by the assert’s falsifying clause. If \( y \) is not equal to \( \max(S) \); \( P_0 \) did not send the correct value. If \( \max(S) \geq mn \); processing should have stopped on the last exchange, and a likely error is \( P_0 \)’s exchange loop condition. If \( mn \neq x \); either a value other than the minimum of \( T \) was chosen, or \( P_0 \) has erroneously altered the variable \( x \) since the last exchange. If the new size of \( S \) has changed, \( P_0 \) has not correctly added or removed a value from \( S \) since the last exchange. If the intersection of \( S \) and \( T \) is not equal to \( y \); either \( S \) or \( T \) has not been correctly updated since the last exchange, and the results of the other clauses help in identifying the incorrect set.
Figure 8.1: Flow Graphs for Set Partition
Figure 8.2: $H$ for Set Partition

Suppose the programmer mistypes line 8 by sending $x$ instead of $mx$ to $P_1$. This mistake is detected by clause $y = \max(S)$ of $A_1$. The negative evaluation of this clause identifies an erroneous value sent by $P_0$. Alternatively, suppose $P_0$'s condition to initiate another exchange is incorrectly $a \geq$ instead of $a >$, then line 7 is

7 while ($mx \geq x$).
This error prevents $P_0$ from detecting the sets are partitioned, and causes SETPART to enter an infinite loop. The clause $mn > x$ of $A_1$ detects this error the first time an invalid exchange is attempted by $P_0$ and eliminates the infinite loop problem.

Static analysis is performed by the algorithms of chapter 7 since loops are present in the program. First, algorithm $\text{CreateFG}_i()$ constructs the control flow graphs. The resulting flow graphs are shown in figure 8.1.
CHAPTER 8. STATIC ANALYSIS OF DISTRIBUTED PROGRAMS

Graph $H$ is constructed by algorithm $\text{Crt} \_H()$ from the flow graphs. The resulting graph $H$ is shown in figure 8.2. The back edge represents the continuous exchange of data between the two processes until the set is partitioned. The $POG$ is constructed from $H$ and is shown in figure 8.3.

Algorithm $\text{Bound} \_\text{Assert}()$ determines the last $LCP'$ event of the assert statement in $P_1$. Node $\text{async} \_\text{recv}(0)$ of $FG_1$ is returned by $\text{Bound} \_\text{Assert}()$. This node is shown in figure 8.1 with double circles. The event $\text{async} \_\text{recv}(0)$ of $P_1$ is represented by two $POG$ nodes. One node has the entry $1:1R0$, and the other node has the entry $2:1R0$.

Starting with node $1:1R0$ of the $POG$, we identify the $LCP$ and $LCP'$ events. The $LCP'$ event is $1:1R0$, and the $LCP$ event is $1:0S1$. For node $2:1R0$, the $LCP'$ event is $2:1R0$, and the $LCP$ event is $2:0S1$. The nodes with double circles in figure 8.3 represent the $LCP$ and $LCP'$ events. Since the assert is in $P_1$, it is not necessary for $P_1$ to propagate state information to $P_0$. Our static analysis allows us to not piggyback messages from $P_0$ to $P_1$.

8.2 Mutual Exclusion

Assume a three process distributed system implements mutual exclusion by embedding the circulating token protocol in its distributed application. Additional assumptions are that process $P_0$ starts the token circulating, process $P_1$ evaluates the the assert statement $A_1$, and each process $P_i$ initializes variable $in \_cs_i$ to false. Assertion $A_1$ detects mutual exclusion violation. The distributed application may incorporate message passing, but we only analyze the mutual exclusion code. The messages of the application will not affect our
analysis. Below is the portion of the code we analyze.

**MUTEX**

\[ P_0:: \]
\[
\begin{align*}
d &\text{do} \\
1 &\text{async.send}(1, \text{token}) \\
2 &\text{async.recv}(2, \text{token}, \text{waitsecs}) \\
3 &\text{if message received} \\
4 &\quad \text{if want.cs} \\
5 &\quad \quad \text{in.cs} = \text{true}; \text{critsec} = \text{false} \\
6 &\quad \quad \text{end if} \\
7 &\quad \text{async.send}(1, \text{token}) \\
8 &\quad \text{else} /* \text{async.recv timed out} */ \\
9 &\quad \quad \text{do.\text{other}0} \\
10 &\quad \quad \text{end if} \\
11 &\text{end do}
\end{align*}
\]

\[ P_1:: \]
\[
\begin{align*}
d &\text{do} \\
13 &\text{async.recv}(0, \text{token}, \text{waitsecs}) \\
14 &\text{if message received} \\
15 &\quad A_1 \quad \text{assert}(\text{in.cs} = t \wedge \text{in.cs} = t \Rightarrow \text{in.cs} \Rightarrow \text{in.cs}) \wedge \text{assert}(\text{in.cs} = t \wedge \text{in.cs} = t \Rightarrow \text{in.cs} \Rightarrow \text{in.cs}) \wedge \text{assert}(\text{in.cs} = t \wedge \text{in.cs} = t \Rightarrow \text{in.cs} \Rightarrow \text{in.cs}) \\
16 &\quad \text{if want.cs} \\
17 &\quad \quad \text{in.cs} = \text{true}; \text{critsec} = \text{false} \\
18 &\quad \quad \text{end if} \\
19 &\quad \text{async.send}(2, \text{token}) \\
20 &\quad \text{else} /* \text{async.recv timed out} */ \\
21 &\quad \quad \text{do.\text{other}1} \\
22 &\quad \quad \text{end if} \\
23 &\text{end do}
\end{align*}
\]

\[ P_2:: \]
\[
\begin{align*}
d &\text{do} \\
24 &\text{async.recv}(1, \text{token}, \text{waitsecs}) \\
25 &\text{if message received} \\
26 &\quad \text{if want.cs} \\
27 &\quad \quad \text{in.cs} = \text{true}; \text{critsec} = \text{false} \\
28 &\quad \quad \text{end if} \\
29 &\quad \text{async.send}(0, \text{token}) \\
30 &\quad \text{else} /* \text{async.recv timed out} */ \\
31 &\quad \quad \text{do.\text{other}2} \\
32 &\quad \quad \text{end if} \\
33 &\text{end do}
\end{align*}
\]
Assume line 26 of $P_2$ is erroneously omitted, and then suppose the following occurs. Process $P_0$ passes the token to $P_1$, and $P_1$ enters its critical section. Process $P_2$ wants to enter its critical section and has set $\text{want.cs}_2$ to true. While $P_1$ is in its critical section, the $\text{async.recv}$ on line 25 times out. The condition of line 27 is true, and $P_2$ incorrectly enters its critical section while $P_1$ is in its critical section.
This invalid critical section entry by $P_2$ is detected by the assert statement $A_1$ when the token circulates around to $P_1$. The clause $(\text{in.cs}_1 = t \land \text{in.cs}_2 = t \Rightarrow \text{in.cs}_1 \rightarrow \text{in.cs}_2 \lor \text{in.cs}_2 \rightarrow \text{in.cs}_1)$ evaluates to false detecting that $P_1$ and $P_2$ entered their critical sections concurrently. The combination of $\text{in.cs}_i$ being true and the timestamp of when $\text{in.cs}_i$ was last modified conveys the last time $P_i$ entered its critical section. With this information, the assert statement detects any of the processes violating mutual exclusion.
CHAPTER 8. STATIC ANALYSIS OF DISTRIBUTED PROGRAMS

The flow graphs for the circulating token protocol are shown in figure 8.4. The do other statements in the source code are represented as a series of assignment nodes in the flow graphs. The H graph generated is shown in figure 8.5, and the POG is shown in figure 8.6.

Algorithm Bound Assert() determines the last LCP' event of the assert statement in P₁, node async_recv(0) of FG₁. This node is shown in figure 8.4 with double circles. The event async_recv(0) of P₁ is represented by two POG nodes. One node has the entry 1:1R0, and the other node has the entry 2:1R0.
CHAPTER 8. STATIC ANALYSIS OF DISTRIBUTED PROGRAMS

Starting with node 1:1R0 of the POG, we identify the LCP and LCP' events. The LCP' event is 1:1R0, and the LCP event is 1:0S1. For node 2:1R0, the LCP' events are 2:1R0, 1:0R2, and 1:2R1. The LCP events are 2:0S1, 1:2S0, and 1:1S2. The nodes with double circles in figure 8.6 represent the events that are the LCP and LCP' events. The messages that implement the circulating token are also the messages that piggyback state information for assert evaluation. The distributed program's application messages will not be tagged for piggybacking.

8.3 Bubble Sort

We continue with the distributed bubble sort program from chapter 2 that consists of six processes. The time space diagram for the bubble sort's execution is repeated in figure 8.7. The hashes on P2's time line represent assertion evaluation. Two asserts in one of the six processes provides a thorough erroneous execution detection method. The assert statements can be in any one of the six processes and provide the same meaningful information. We have arbitrarily selected P2. Process P2's source code is shown below with the two assert statements A2a and A2b. The clause \( P_i.list \leq P_i.recv_i.list \) in the assert statements tests whether every element in \( P_i.list \) is less than or equal to all elements of \( P_i.recv_i.list \). and the clause \( P_i.list \geq P_i.recv_i.list \) in the assert statements tests whether every element in \( P_i.list \) is greater than or equal to all elements \( P_i.recv_i.list \).
P2::

    integer pid, phase;
    arrays list, recv_list
    pid = 2
    read q/6 elements into list
    sort list
    for phase = 0 to 5
      if phase is even
        async_send(3, list)
        async_recv(3, recv_list)
        list = merge_sort(list, recv_list, first)
        assert( P2.list ≤ P2.recv_list ∧ P2.recv_list = P3.list ∧
                P3.list ≤ P3.recv_list ∧ P3.recv_list = P4.list ∧
                P4.list ≤ P4.recv_list ∧ P4.recv_list = P5.list ∧
                P5.list ≥ P5.recv_list )
      endif
      if phase is odd && pid != 0 && pid != N - 1
        async_send(1, list)
        async_recv(1, recv_list)
        list = merge_sort(list, recv_list, last)
        assert( P2.list ≥ P2.recv_list ∧ P2.recv_list = P1.list ∧
                P1.list ≥ P1.recv_list ∧ P1.recv_list = P0.list ∧
                P0.list ≤ P0.recv_list )
      endif
    endfor

merge_sort(list, recv_list, half)::

    array merge_list
    merge_list = merging of recv_list and list
    sort merge_list
    if half = first
      return first half of elements in merge_list
    else
      return last half of elements in merge_list
    endif

The clause \( P_i.recv_list = P_{i+1}.list \), for \( i = 2 \ldots 4 \), of assert \( A_{2a} \) determines whether process \( P_i \) received the correct list from its right neighbor \( P_{i+1} \). The clause \( P_i.recv_list = P_{i-1}.list \), for \( i = 1 \ldots 2 \), of assert \( A_{2b} \) determines whether process \( P_i \) received the correct
list from its left neighbor $P_{i-1}$. The clauses $P_i.list \leq P_i.recv.list$ and $P_i.list \geq P_i.recv.list$ ensure that $\text{merge}_\text{sort}()$ correctly sorted and halved the merged list.

Assume line 9 of $P_i$ is mistyped. The function $\text{merge}_\text{sort}()$ is passed $\text{last}$ instead of $\text{first}$. Function $\text{merge}_\text{sort}()$ sorts and returns the last $q/6$ elements, and these elements are assigned to $\text{list}$. The correct execution should have assigned to $\text{list}$ the first $q/6$ elements of the merged and sorted elements. In the next phase (odd), line 12 of $P_i$ sends this incorrect $\text{list}$ to $P_3$. Assume $P_3$ is correct. In the following even phase when $P_3$ sends its supposedly correct list to $P_2$, the clause $P_3.list \leq P_4.recv.list$ of assert $A_{2a}$ evaluates to false detecting that $P_4$ executed incorrectly. This false evaluation singles out the error to $P_4$'s execution.
of `merge_sort()` in an even phase. In general, errors in merging, sorting and halving

```
Figure 8.8: Flow Graphs for Bubble Sort
```

any of the process's list will be detected by the two assert statements. The comparisons

\[ P_2.list \leq P_2.recv.list, \quad P_3.list \leq P_3.recv.list \quad \text{and} \quad P_4.list \leq P_4.recv.list \]

of \( A_{28} \) ensures the correct execution of \( P_2 \) and its right neighbors. The comparisons

\[ P_2.list \geq P_2.recv.list \quad \text{and} \quad P_1.list \geq P_0.recv.list \]

of \( A_{28} \) ensures the correct execution of \( P_2 \) and its left neighbors.
In an even phase, process $P_3$ should send list to $P_2$. But consider the case when $P_3$ mistakenly sends recv \_list instead of list. Clause $P_2.\text{recv}_\_\text{list} = P_3.\text{list}$ of $A_{2a}$ evaluates to false and identifies $P_2$ as sending the incorrect data. Assert $A_{2a}$ ensures that $P_2$'s right neighbors have sent the correct data, and assert $A_{2b}$ ensures that $P_2$'s left neighbors have sent the correct data.
CHAPTER 8. STATIC ANALYSIS OF DISTRIBUTED PROGRAMS

The source code for the other five processes is not shown in this chapter, but the bubble sort algorithm in chapter 2 is sufficiently outlined for our static analysis. The flow graphs are shown in figure 8.8. The resulting $H$ graph is shown in figure 8.9. Each process has an if/else branch in execution, and the combinations of different executions creates a large $H$ graph. Only those branches that contribute to a path in the $POG$ are shown in $H$. An edge with an asterisk denotes an incorrect decision made at the if/else branch of the processes. The resulting $POG$ is shown in figure 8.10.

Since we have two assert statements in $P_2$, algorithm $Bound\_Assert()$ is called twice to determine the last $LCP'$ events. For assert $A_{2a}$, the last $LCP'$ event is $async\_recv(3)$ of $FG_2$. The event $async\_recv(3)$ is represented by three $POG$ nodes. The $POG$ node entries that represent this receive are 1:2R3, 3:2R3, and 2:2R3. For assert $A_{2b}$, the last $LCP'$ event is $async\_recv(1)$ of $FG_2$. The event $async\_recv(1)$ is also represented by three $POG$ nodes. The $POG$ node entries that represent this receive are 2:2R1, 1:2R1, and 2:2R1. All six $POG$ node representatives of these last $LCP'$ events are underlined in figure 8.10.

For each of the last $LCP'$ events, the $LCP$ and $LCP'$ events are determined by algorithm $Find\_LCPs()$. The $LCP$ and $LCP'$ events are underlined in figure 8.11. The messages that piggyback state information are shown in the time space diagram of figure 8.7 as solid directional lines. The $LCP$ and $LCP'$ events for assert $A_{2a}$ are identical to the $LCP$ and $LCP'$ events for assert $A_{2b}$. In this example, the additional assert statement did not increase the number of messages piggybacking state information.

8.4 Tree Sort

Referring back to figure 2.5, we see that the distributed tree sort program of chapter 2 consists of 15 processes. We have selected $P_1$ to evaluate assert statement $A_1$. This assertion ensures that processes $P_1, P_3, P_4, P_7, P_8, P_9$ and $P_{10}$ have correctly split, merged, and sorted the list $P_0$ sent to $P_1$. Since the left side and the right side of the tree are symmetric, a similar assert statement would be placed in $P_2$ to ensure processes $P_2, P_5, P_6, P_{11}, P_{12}, P_{13}$ and $P_{14}$ correctly split, merge, and sort the list $P_0$ sent to $P_2$.

$P_1::$ (parent node)
  integer $child_1, child_2, parent$
  arrays $list, list_1, list_2$
  1 async_recv(0, list);
  2 split list into two halves: $list_1, list_2$
  3 async_send(3, $list_1$)
  4 async_send(4, $list_2$)
  5 async_recv(3, $list_1$)
  6 async_recv(4, $list_2$)
  $A_1$: assert($P_7.list$ is sorted $\land$ $P_8.list$ is sorted $\land$ $P_9.list$ is sorted $\land$
                 $P_{10}.list$ is sorted $\land$ $P_3.list$ is sorted $\land$ $P_4.list$ is sorted $\land$
                 $((P_7.list \cup P_8.list \cup P_9.list \cup P_{10}.list) = P_1.list) \land$
                 ($P_7.list = P_3.list_1) \land$ ($P_8.list = P_3.list_2) \land$
                 (($P_3.list_1 \cup P_3.list_2) = P_3.list = P_1.list_1) \land$
                 ($P_9.list = P_4.list_1) \land$ ($P_{10}.list = P_4.list_2) \land$
                 ($P_3.list_1 \cup P_3.list_2 = P_3.list = P_1.list_2) \land$
                 ($P_1.list_1 \cup P_1.list_2 = P_1.list)$)
  7 merge $list_1$ and $list_2$ into $list$
  8 async_send(0, list)

In the correct implementation of tree sort, $P_3$ receives a list from $P_1$, and then $P_3$ is responsible for sorting this list and sending the sorted list to $P_1$. Assume $P_3$ erroneously sends the wrong list to $P_1$. Following is the incorrect implementation of $P_3$: 

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
Figure 8.12: Flow Graphs for Tree Sort

\( P_3 :: (\text{parent node}) \)

\[
\begin{align*}
\text{integer} & \quad \text{child}_1, \text{child}_2, \text{parent} \\
\text{arrays} & \quad \text{list}, \text{list}_1, \text{list}_2 \\
1 & \quad \text{async} \_\text{recv}(1, \text{list}); \\
2 & \quad \text{split list into two halves: } \text{list}_1, \text{list}_2 \\
3 & \quad \text{async} \_\text{send}(7, \text{list}_1) \\
4 & \quad \text{async} \_\text{send}(8, \text{list}_2) \\
5 & \quad \text{async} \_\text{recv}(7, \text{list}_1) \\
6 & \quad \text{async} \_\text{recv}(8, \text{list}_2) \\
7 & \quad \text{merge } \text{list}_1 \text{ and } \text{list}_2 \text{ into } \text{list} \\
8 & \quad \text{async} \_\text{send}(1, \text{list}_1)
\end{align*}
\]

Line 8 is incorrect. \( P_3 \) should send \( \text{list} \) to \( P_1 \). Assert \( A_1 \) detects the error by two clauses evaluating to false. These clauses are \( (P_3.\text{list}_1 \cup P_3.\text{list}_2 = P_3.\text{list} = P_1.\text{list}_1) \) and
(\(P_1\.list_1 \cup P_1\.list_2 = P_1\.list\)). The combination of these clauses identifies that \(P_1\.list_1\) is incorrect. Since none of the other clauses involving \(P_3\.list_1\) and \(P_3\.list_2\) evaluated to false, the false evaluation of \((P_3\.list_1 \cup P_3\.list_2 = P_3\.list = P_1\.list_1)\) conveys that \(P_1\.list_1\) is not equal to \(P_3\.list\). With this information, the source of the error is easily found.

As another example of an incorrect implementation, suppose leaf process \(P_8\) does not correctly sort its list. This error causes clause \((P_8\.list\ is\ sorted)\) of \(A_1\) to evaluate to false. None of the other clauses evaluate to false, and the source of the error is directly identified.

The flow graphs for \(P_0\), \(P_1\), \(P_2\), and \(P_7\) are shown in figure 8.12. The flow graphs for \(P_3\), \(P_4\), \(P_5\) and \(P_6\) are identical to \(P_2\)'s flow graph with the exception of the destination and source of messages. Also, the flow graphs for \(P_8\), \(P_9\), \(P_{10}\), \(P_{11}\), \(P_{12}\), \(P_{13}\), \(P_{14}\) are identical to \(P_7\)'s flow graph with the exception of the destination and source of the message. The destinations and originations of the messages for the communication events are given in chapter 2.

The \(H\) graph for the tree sort program is shown in 8.13. There exists only one execution path since none of the processes have a possible branch in execution. The resulting \(POG\) is shown in figure 8.14. Algorithm \texttt{Bound Assert}() returns the event \texttt{async_recv(4)} of \(P_2\) as the last \(LCP'\) event. This event is identified in \(P_1\)'s flow graph with double circles.

One \(POG\) node represents this receive event, and that node's entry is 3:1R4. This event, as well as the \(LCP\) and \(LCP'\) events determined by algorithm \texttt{Find_LCPs}(), is underlined in figure 8.14. Figure 8.15 is the time space diagram of tree sort's execution with the six messages that piggyback state information shown as solid lines.

8.5 Positive Acknowledgement/Retransmission

The two process distributed program implementing positive acknowledgement and retransmission is repeated from chapter 2 with the addition of assert statement $A_0$. Process $P_0$ sends a message to $P_1$, and $P_1$ acknowledges receipt of that message. Process $P_0$ retransmits the message until an acknowledgement for the message is received.

$P_0::$

\[
\text{MsgBitSend : bit} \\
\text{sbbuffer: message} \\
\text{event: (MsgArrival, CksumErr, TimeOut)}
\]

\[
1 \quad \text{MsgBitSend = 0} \\
2 \quad \text{FromHost(sbbuffer)} \\
3 \quad \text{repeat}
\]

P1::
MsgBitReceive : bit /* alternating bit */
IncomingBit : bit /* incoming message’s bit */
rbuffer: message /* buffer for incoming data message */
event: (MsgArrival, CksumErr) /* different interrupt events */
MsgBitReceive = 0 /* initialize alternating bit */
repeat
wait(event) /* possibilities MsgArrival, CksumErr */
if event = MsgArrival /* a valid message has arrived */
async_recv(0, rbuffer, IncomingBit) /* accept the message */
if IncomingBit = MsgBitReceive
ToHost(rbuffer) /* pass the data to the host */
inc(MsgBitReceive) /* increment by 1 then mod 2 */
endif
async_send(0, acknowledgement)
endif
until doomsday

Assert A0 first determines if IncomingBit was correctly received at P1 and was not erroneously changed by P1. The second clause of the assert, P0.MsgBitSend \( \neq \) P1.MsgBitReceive, ensures that MsgBitSend and MsgBitRecv are correctly updated. The third clause, P0.sbuffer = P1.rbbuffer, determines whether P1 received the correct message, and the last clause, P1.event = MsgArrival, ensures that P1 sent the acknowledgement only after it received a message from P0.
In the correct implementation of this distributed program, process $P_i$ increments $MsgBitReceive$ when a new message is received. Suppose $P_i$ increments $MsgBitReceive$ when it receives any valid message. This error occurs if either line 18 is omitted or if line 20 is placed after line 21.

Assume line 18 is omitted. Suppose the following events occur. $P_0$ sends a message to $P_1$. $P_1$ receives the message and correctly passes the message to the host and increments $MsgBitReceive$. Process $P_1$ then sends an acknowledgement, but the acknowledgement is
lost. Process \( P_0 \) times out and retransmits the same messages. Process \( P_1 \) receives a
duplicate message. Since line 18 is missing, \( P_1 \) erroneously passes the message to the host
and increments \( \text{MsgBitReceive} \). Process \( P_1 \) then sends an acknowledgement to \( P_0 \), and the
acknowledgement is received by \( P_0 \). The assert statement is evaluated. The second clause
of \( A_0 \cdot P_0 \cdot \text{MsgBitSend} \neq P_1 \cdot \text{MsgBitReceive} \). evaluates to false and identifies the error.

As another example of an incorrect implementation, assume \( P_1 \) sends an acknowledgement
for any event. This error occurs if line 22 is placed after line 23. Suppose the following
events occur. Process \( P_0 \) sends a message to \( P_1 \). The message is corrupted in transit. Process
\( P_1 \) is interrupted and procedure wait returns a CKsumErr event. Line 16 evaluates to
false, but then \( P_1 \) incorrectly sends an acknowledgement to \( P_0 \). Process \( P_0 \) receives the ack-
nowledgement. The assert statement is then evaluated, and clause \( P_1 \cdot \text{event} = \text{MsgArrival} \)
evaluates to false. This clause identifies that \( P_1 \) sent an invalid acknowledgement.

The flow graphs are shown in figure 8.16, and graph \( H \) in shown in figure 8.17. Although
the two processes’ source code is short, the execution behavior of the distributed program
is complex. The main reason for this is the `async_recv(1, ack)` of line 8. Process \( P_1 \) will continue execution regardless of whether \( P_0 \) receives \( P_1 \)'s acknowledgement. The result, as shown in figure 8.17, is multiple branches of execution. The resulting POG is shown in figure 8.18.

The assert statement is evaluated when the if condition of \( P_0 \) evaluates to true. Algorithm `Bound_Assert()` identifies statement `async_recv(1)` of \( P_0 \) as the last \( LCP' \) event. This event is represented by three POG nodes which are underlined in figure 8.18. Only the messages sent from \( P_0 \) to \( P_1 \) need to piggyback state information. Algorithm `Find_LCPs()` identifies the POG node entries that represent the send event of \( P_1 \) as the \( LCP \) event. Both \( LCP \) and \( LCP' \) events are underlined in the POG of figure 8.19.
The five examples analyzed in this chapter are diverse in their communication behavior. Together they demonstrate the robustness of our static analysis technique. For each example, the analysis identifies the latest causally preceding communication events. The assert is evaluated with the causal global state obtained by piggybacking state information on the messages of the $LCP$ and $LCP'$ events.

### 8.6 Prototype

A prototype system has been written to demonstrate the feasibility of analyzing distributed programs for evaluating distributed asserts. Our prototype is a two-pass compiler. The grammar for our compiler is shown in appendix A. The C source files for the distributed processes are the input of the compiler. For assert statement evaluation, code is added
to the processes' source files to create and maintain a causal global state, and the LCP messages are identified and altered to piggyback this causal global state. The remainder of the distributed program is not altered.

We will use the distributed program SETPART as our running example in the following explanation of our system. The source code for SETPART appears below.

Po:

```c
#include <stdio.h>
#include <async.h>
#include <sys/time.h>

int S[16];
int x;

main(argc,argv)
    int argc;
    char *argv[];
{
    int count;
    int numcount;
    int len;
    int i;
    int mx;

    if (argc < 2)
        {
            fprintf ( stderr, "USAGE: %s <st size>\n", argv[0]);
            exit(1);
        }

    init_async (121, 0, 2, 0, 0.0, 0, 0 );
    count = atoi(argv[1]);
    Init_List ( S, &numcount, count, 0); 

    printf("Initial set in P0\n\t");
    for ( i=0; i<numcount; i++ )
        printf("%6d ", S[i]);
    printf("\n\n");

    mx = max( S );
    x = -99999;
    while (mx > x)
```
\{ async\_send ( 1, \&mx, sizeof(mx) );
    Remove ( S, \&numcount, mx );
    len = sizeof(int);
    async\_recv ( 1, \&x, \&len, 60 );
    Add ( S, \&numcount, x );
    mx = max( S );
\}

printf("Final set in P0\n\t");
for ( i=0; i<numcount; i++ )
    printf("%6d ", S[i]);
printf("\n\n");
close\_async();

P1
#include <stdio.h>
#include <async.h>
#include <sys/time.h>

int mn;
int T[16];
int y;

main(argc,argv)
    int argc;
    char *argv[];
{ int count;
    int numcount;
    int len;
    int i;
    int devdata;

    devdata = 1;
    if (argc < 2)
        {
            printf ( stderr, "USAGE: %s <set size>\n", argv[0]);
            exit(1);
        }
    init\_async ( 121, 1, 2, 0, 0.0, 0, 0 );
    count = atoi(argv[1]);
    numcount = Init\_List ( T, \&numcount, count, 1);

printf("Initial set in P1\n\t");
for ( i=0; i<numcount; i++ )
    printf("%6d ", T[i]);
printf("\n\n");
while (devdata > 0)
{
    len = sizeof(int);
    devdata = async_recv ( 0, &y, &len, 60 );
    if (devdata > 0)
    {
        Add ( T, &numcount, y );
        mn = min( T );
        assert((max(CG._PO_S.S) == y) &&
                (max(CG._PO_S.S) >= mn) &&
                (mn > CG._PO_x.x) &&
                (intersect(CG._PO_S,S, T) == y));
        async_send ( 0, &mn, sizeof(mn) );
        Remove ( T, &numcount, mn );
    }
}

printf("Final set in P1\n\t") ;
for ( i=0; Knumcount; i++ )
    printf("%6d ", T[i]);
printf("\n\n") ;
close_async();

The first pass of our compiler consists of four phases. The initial phase parses the source code in each of the process input files and creates a control flow graph for each process as described in chapter 7. A declaration table, VarMap, is created. Each variable in a process has an entry in the table consisting of variable type, identifier and amount of memory required.

When an assert statement is detected by the parser, an entry containing only the variable identifier is added to the list assert vars for each non-local variable that occurs in the assert. Since processes can have identical variable identifiers, a notation has been developed to distinguish the process in which a variable resides. Non-local variables of the assert must be specified in the following format:

CG._Pi.id.id
The process number is indicated by \( i \), and the \textit{ids} indicate the variable identifier. For example, set partition's assert is

\[
\text{assert}((\text{max}(\text{CG}.\text{PO}.S.S) == y) \ \&\& \\
(\text{max}(\text{CG}.\text{PO}.S.S) >= \text{mn}) \ \&\& \\
(\text{mn} > \text{CG}.\text{PO}.x.x) \ \&\& \\
(\text{intersect}(\text{CG}.\text{PO}.S.S, T) == y));
\]

The list \textit{assert.vars} will have two entries, \text{CG}.\text{PO}.S.S and \text{CG}.\text{PO}.x.x, after parsing this assert.

The second phase creates three files for each process: \text{asserti.h}, \text{pigRecvi.c}, and \text{pigSendi.c} where \( i \) is the process number. Each \text{asserti.h} file defines a data structure for the causal global state and will be included in \( P_i \). A structure exists in the included file for each entry of \textit{assert.vars}. The type and size of each item of \textit{assert vars} are found in the table \textit{VarMap}. The singular difference between \text{asserti.h} and \text{assertj.h} is the initialization of vector time. The files \text{assert0.h} and \text{assert1.h} created for SETPART are shown below.

\text{assert0.h}:

```c
#define MAXPS 2
struct
{
    struct
    {
        int S[16];
        int vtime;
    } _PO_S;
    struct
    {
        int x;
        int vtime;
    } _PO_x;
} CG, tmpCG;
int _vector_t[MAXPS] = {1, 0 };
```

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
assert1.h:
#define MAXPS 2
struct
{
    struct
    {
        int S[16];
        int vtime;
    } _P0_S;
    struct
    {
        int x;
        int vtime;
    } _P0_x;
} CG, tmpCG;
int _vector_t[MAXPS] = {0,1};

The symbol MAXPS indicates the number of processes in the distributed program. As shown in procedure Update() of chapter 4, the integer vtime is used for updating the causal global state. The variable CG is the causal global state, and the variable tmpCG is for temporarily holding a received causal global state. Vector time is maintained in the array _vector_t[].

The file pigSend1.c is included by process $P_i$. This file contains the source code for function Piggy_Send() which piggybacks the causal global state onto an outgoing message. This function is also responsible for updating the causal global state prior to piggybacking state information. The Piggy_Send() functions differ for each process. Piggy_Send() for process $P_i$ is only responsible for updating CG with the variables that reside locally in $P_i$.

The files pigSend0.c and pigSend1.c for SETPART are shown below.

PigSend0.c
#include <stdio.h>
#include <async.h>
Piggy_send(i, data, sizedata)
CHAPTER 8. STATIC ANALYSIS OF DISTRIBUTED PROGRAMS

```c
int i;
char *data;
int sizedata;
{
    char *dataptr;

    dataptr=(char *)malloc(sizeof(CG)+sizedata);
    memcpy(dataptr, data, sizedata);
    memcpy(CG._P0_S.vtime, _vector_t[0];
    CG._P0_S.vtime = _vector_t[0];
    CG._P0_x.vtime = _vector_t[0];
    memcpy((dataptr+sizedata), &CG, sizeof(CG));

    return(async_send(i, dataptr, sizeof(CG)+sizedata));
}

PigSend1.c
#include <stdio.h>
#include <async.h>
Piggy_send(i, data, sizedata)
int i;
char *data;
int sizedata;
{
    char *dataptr;

    dataptr=(char *)malloc(sizeof(CG)+sizedata);
    memcpy(dataptr, data, sizedata);
    memcpy((dataptr+sizedata), &CG, sizeof(CG));

    return(async_send(i, dataptr, sizeof(CG)+sizedata));
}
```

The file pigRecvi.c is included by process $P_i$. This file contains the source code for function Piggy_Recv() which receives an incoming message that has been piggybacked with a causal global state. The newly received causal global state is copied into the variable tmpCG. The Piggy_recv() of $P_i$ updates $P_i$'s causal global state with the latest state information by comparing the vtime of corresponding entries in CG and tmpCG. The entry with the largest vtime has the latest state information. This is consistent with the causal state propagation protocol described in chapter 4. Piggy_recv() of $P_i$ only updates the components of the
causal global state that do not correspond to its own variables. The files pigRecv0.c and pigRecv1.c for SETPART are shown below.

pigRecv0.c:

```c
#include <stdio.h>
#include <async.h>
PIggys_recv(i, data, sizedata, time)
  int i;
  char *data;
  int *sizedata;
  int time;
{
  char *dataptr;
  int CGsize;

  CGsize = sizeof(CG) + *sizedata;
  dataptr=(char *)malloc(CGsize);

  if (async_recv(i, dataptr, &CGsize, time) < 0)
    return(-1);
  *sizedata = CGsize - sizeof(CG);
  memcpy(data, dataptr, *sizedata);
  memcpy(fctmpCG, (dataptr + *sizedata), sizeof(CG));
  return(*sizedata);
}
```

pigRecv1.c:

```c
#include <stdio.h>
#include <async.h>
PIggys_recv(i, data, sizedata, time)
  int i;
  char *data;
  int *sizedata;
  int time;
{
  char *dataptr;
  int CGsize;

  CGsize = sizeof(CG) + *sizedata;
  dataptr=(char *)malloc(CGsize);

  if (async_recv(i, dataptr, &CGsize, time) < 0)
    return(-1);
  *sizedata = CGsize - sizeof(CG);
  memcpy(data, dataptr, *sizedata);
  memcpy(&tmpCG, (dataptr + *sizedata), sizeof(CG));
```
if (CG._P0_S.vtime < tmpCG._P0_S.vtime)
{ memcpy(CG._P0_S.S, tmpCG._P0_S.S, (sizeof(int) * 16));
  CG._P0_S.vtime = tmpCG._P0_S.vtime;
}
if (CG._P0_x.vtime < tmpCG._P0_x.vtime)
{ memcpy(&CG._P0_x.x, &tmpCG._P0_x.x, sizeof(CG._P0_x.x));
  CG._P0_x.vtime = tmpCG._P0_x.vtime;
}
return(*sizedata);
}

The third phase determines the \(LCP\) and \(LCP'\) events. The \(H\) graph and the \(POG\) are constructed according to the algorithms \(Crt.H\) and \(Crt.POG\) given in chapter 7. From the \(POG\), the \(LCP\) and \(LCP'\) events are determined. These events are found according to the algorithms \(BoundAssert\) and \(FindLCPs\) also of chapter 7. This phase produces the same results for \(SETPART\) that were given in section 8.1.

The last phase of pass one forks a child process that is the second pass of the compiler and establishes a pipe from the first pass process to the second pass process. Through this pipe the identification of the \(LCP\) and \(LCP'\) events are sent to the second pass. The identification of each event consists of two numbers: process identifier and communication node identifier. As the nodes of the control flow graph are created in phase one, a counter \texttt{commoNodeID} is assigned to each communication node. The counter \texttt{commoNodeID} is initialized to one each time a new control flow graph is built and incremented each time an \texttt{async.recv} or \texttt{async.send} node is added.

The second pass of the compiler reads the \(LCP\) and \(LCP'\) event identifications and stores this information in the table \texttt{IDMap}. The distributed processes are parsed again by pass two, and a new source file is created for each process. The name of each file is \texttt{H\_file.c},

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
where file is the name of the original source file. If the names of SETPART’s original source files are proc0.c and proc1.c, then N.proc0.c and N.proc1.c are the two new source files created by pass two. These new source files are the result of altering the original files to incorporate piggybacking of data on the LCP and LCP’ events.

The first line written in process P_i’s new file is #include “asserti.h”. When a line of source code is read by the parser that is not an async_send() or async_recv() function call that corresponds to an LCP or LCP’ event, the line is written to the new source file. The parsing of pass two does not create internal data structures, only a commoNodeID counter is maintained as in pass one. When a send or receive command is detected during parsing, the commoNodeID is incremented and the table IDMap is checked to determine if the command is an LCP or LCP’ event. If the command is an LCP or LCP’ event and is an async_send() function call, the function name is replaced with Piggy_send. The parameters of the function are not altered. A line is also added after the function call to update vector time. If the command is an LCP or LCP’ event and is an async_recv() function call, the function name is replaced with Piggy_recv. Again the parameters of the function are not altered, and a line is added after the function call to update vector time.

After the source file for P_i has been parsed, two lines are added to the end of the new source file to include the pigRecv.i.c file and the pigSend.i.c file, thus completing the creation of the new file. Once all new source file are created, our two pass compiler is finished. The new files for SETPART are shown below.

N.proc0.c:

#include "assert0.h"
#include <stdio.h>
#include <async.h>
#include <sys/time.h>

int S[16];
int x;

main(argc, argv)
   int argc;
   char *argv[];
{
   int count;
   int numcount;
   int len;
   int i;
   int mx;

   if (argc < 2)
      {
      fprintf(stderr, "USAGE: %s <st size>\n", argv[0]);
      exit(1);
      }

   init_async(121, 0, 0, 0, 0, 0, 0, 0);
   count = atoi(argv[1]);
   Init_List(S, &numcount, count, 0);

   printf("Initial set in P0\n\t");
   for (i=0; i<numcount; i++)
      printf("%6d ", S[i]);
   printf("\n\n");

   mx = max(S);
   x = -99999;
   while (mx > x)
      {
      Piggy_send(1, &mx, sizeof(mx));
      _vector_t[0]++;

      Remove(S, &numcount, mx);
      len = sizeof(int);
      async_recv(1, &x, &len, 60);
      _vector_t[0]++;

      Add(S, &numcount, x);
      mx = max(S);
      }

   printf("Final set in P0\n\t");
   for (i=0; i<numcount; i++)
      printf("%6d ", S[i]);
}
printf("%6d ", S[i]);
printf("\n\n");

close_async();
}
#include "pigRecvO.c"
#include "pigSendO.c"

N.proc1.c:

#include "asserti.h"
#include <stdio.h>
#include <async.h>
#include <sys/time.h>

int mn;
int T[16];
int y;

main(argc,argv)
 int argc;
 char *argv[];
{
 int count;
 int numcount;
 int len;
 int i;
 int devdata;

 devdata = 1;
 if (argc < 2)
  {
   fprintf ( stderr, "USAGE: %s <set size>\n", argv[0]);
   exit(1);
  }
 init_async ( 121, 1, 2, 0, 0.0, 0, 0 );
 count = atoi(argv[1]);
 numcount = Init_List ( T, &numcount, count, 1);

 printf("Initial set in Pi\n\t");
 for ( i=0; i<numcount; i++ )
  printf("%6d ", T[i]);
 printf("\n\n");

 while (devdata > 0)
  {
   len = sizeof(int);
   devdata = Piggy_recv(0, &y, &len, 60);
The new files are ready for compilation and execution. After compilation, the executing programs create and maintain a causal global state for the assert statements. The assert statement is evaluated using the causal global state transmitted via the identified \textit{LCP} messages. Despite the potential disturbance to the timing of the distributed program's execution by increasing message sizes, the timing changes of our technique are minor compared to other existing techniques. We do not add messages to the distributed execution and execution is not suspended to gather state information. By preserving the causal relationships, the distributed program maintains the same functionality of the original.
Chapter 9

Conclusions

Our research addresses the difficult issue of monitoring the execution of a distributed system. We have developed a runtime method for monitoring both stable and unstable properties that does not disrupt the computation of the distributed system. We used the sequential assert statement as the basis for our development of the distributed assert statement. A distributed assert statement is evaluated with that statement's causal global state. The causal global state incorporates the state of the system as a whole as it may have causal impact upon the assert statement.

We have developed a runtime protocol that constructs the causal global state and evaluates the assert statement where no additional synchronization or message passing is imposed on the distributed application. The causal global state is immediately available providing real-time feedback.

The protocol increases the size of only the messages corresponding to the $LCP$ and $LCP'$ events. We refined our protocol by statically analyzing the distributed program in order to reduce the amount of piggybacked data. Our techniques are able to analyze complex
distributes programs where each process has branches in execution and nested loops. The POG is able to represent all concurrent and causal relationships and all possible paths of the system's execution. By having this information condensed into the POG, we are able to determine the assert's $LCP$ and $LCP'$ events.

In conclusion, our work provides a practical solution for monitoring a distributed system's execution that is not only theoretically sound, but also implementable. Our solution provides a powerful monitoring tool that can be used throughout the system's life cycle. and the only responsibility left to the distributed program developer is to assert predicates as needed. The developer must understand causality to create informative predicates since they will be evaluated with a causal global state.

9.1 Communication Systems

Two message passing systems are commonly used for writing distributed programs. These systems are PVM (Parallel Virtual Machine) and MPI (Message Passing Interface). Both can run on a variety of architecture platforms and provide a library of communication commands. Our work has not been ported to these systems, but we will address what would be involved.

PVM is the forerunner of MPI. PVM provides asynchronous reliable FIFO point-to-point communication on a heterogeneous network of machines running Unix. A process sends a message to another process with the command `pvm_send()`. The `pvm_send()` has the same functionality as our `async_send()`. A process receives a message with one of the following commands: `pvm_recv()`, `pvm_trecv()`, or `pvm_nrecv()`. The command `pvm_recv()` is a
blocking receive and is equivalent to our `async_recv()`. As with our `async_recv()`, there is an option to receive from any process instead of a specific process. This is achieved with a -1 in the process identification field. We have not addressed this issue in our analysis, although only minor modifications are necessary to handle the -1 option. Consider a four process system with the following line in process $P_0$.

```
async_recv(-1, y)
```

In terms of flow of execution, this is equivalent to the nested if/else statements shown below. Since all paths of executable are assumed possible in our analysis, boolean expressions are not necessary and the textual order of the receiving processes is irrelevant in the nested if/else statements.

```
if ()
    async_recv(1, y)
else if ()
    async_recv(2, y)
else if ()
    async_recv(3, y)
```

We are able to analyze communication commands embedded in nested if/else statements. The only modification required to our analysis is to recognize the -1 option and treat this as nested if/else statements.

The command `pvm_trecv()` is a blocking receive with the ability to timeout after a specified length of time. The command `pvm_nrecv()` is non-blocking receive. If a message has not arrived when `pvm_nrecv()` is executed, it returns immediately. Our `async_recv()` has an option of specifying a length of time to wait for a message. Setting this field to zero is equivalent to a nonblocking receive. We did not explicitly address nonblocking and timeout.
receives, but they can be analyzed with minor modifications. Consider a four process system with the following line in process $P_0$.

\[ \text{async\_recv}(1, y, 0) \]

The zero is the timeout. In terms of execution flow, this is equivalent to the if statement shown below.

\[
\begin{align*}
\text{if} &() \\
&\text{async\_recv}(1, y)
\end{align*}
\]

The only change to our analysis is to recognize the use of the timeout field and to analyze in the same manner as an if statement and a receive command.

Multicasting is also possible in PVM. The command \texttt{pvm\_mcast()} is executed by the sender of the multicast message. The sender of the multicast messages may send to all processes except itself. An array of process identifiers is provided to the command \texttt{pvm\_mcast()} specifying which processes should be sent the message. We do not have an equivalent command in our asynchronous library. If the array contains the values 1 and 2, this is equivalent to two asynchronous send commands, one sending to $P_1$ and one sending to $P_2$. Our analysis is able to handle a sequential series of send commands. The modifications necessary to analyze a multicast command are to read the pids from the array and treat each entry as a separate send command.

MPI provides reliable FIFO communication which can be either asynchronous or synchronous indicated by the send command. Communication can also be either blocking or
nonblocking. Both the send and receive commands indicate whether blocking is desired. MPI's and PVM's blocking have different semantics. MPI attempts to improve system performance by overlapping communication and computation. Nonblocking communication is one way to achieve this overlap. A nonblocking send is initiated with a command that copies the message to a buffer and immediately returns. While computation is preceding, the message is copied out of the send buffer. The send is completed with a command to verify that the message has been transferred. Similarly, a receive command initiates the receive operation and immediately returns. While computation continues, data is transferred into the receive buffer. A separate command completes the receive operation.

MPI's library of communication commands is large, and it is not necessary to discuss each command. We will describe how each type of communication can be achieved with a subset of the commands. Asynchronous communication can be achieved with the communication pair `MPI_BSend()` and `MPI_Recv()`. The B preceding Send indicates that message buffering is to be used. The send blocks by default, meaning the send will wait until the message is copied out of the sender's buffer before it returns control to the caller. The receive also blocks by default, meaning it returns only after the receive buffer contains the message. MPI's blocking asynchronous communication can be analyzed as we currently analyze our `async_send()` and `async_recv()`.

Nonblocking communication is indicated with an I in the communication commands: `MPI_IBSend()` and `MPI_IRecv()`. The command `MPI_IBSend()` places the message in the buffer. The command `MPI_Test()` verifies that the send has completed. We only need to analyze the `MPI_IBSend()`, and it can be analyzed in the same manner as `async_send()`.
The contents of the send buffer reflect the causal information of the sending process. The computation that occurs between the `MPI_IBSend()` and `MPI_Test()` do not affect the causal global state and can be considered as occurring after the send. The command `MPI_IRecv()` only initiates the receiving of the message. The command `MPI_WAIT()` is one of several commands that can complete the receive. The command `MPI_WAIT()` waits for the receive to complete. The commands that complete the receipt of the message should be analyzed in the same manner as `async_recv()` since this is when the message is received by the process.

The commands for synchronous communication are `MPI_SSend()` and `MPI_Recv()`. Our work will require modifications to analyze synchronous communication. Synchronous message passing means that the sending process blocks until the message is received by the destination process. We discussed synchronous communication when describing Taylor's work in chapter 6. Since the rendezvous of a send/receive pair in the synchronous domain can be considered a single event on the sending and receiving processes, the algorithms for constructing the POG and the $H$ will require modification to correctly represent the happens before relationships. The algorithms for finding the $LCP$ and $LCP'$ events will also require minor modifications.

MPI's communication commands have the same options that are available with PVM's commands. We discussed the analysis of these options when describing PVM. For example, the MPI receive command also has a wild card to indicate it will accept a message from any process. MPI also provides commands for broadcasting. The analysis of these broadcast commands can be handle in the same manner as with PVM multicast commands.
In conclusion, the major work for analysis programs written in either of these two message passing systems is for synchronous communication. As described, the remaining work will require minor modifications for recognizing the particular system's asynchronous communication commands.

9.2 Complexity issues of static analysis

The worst case performance of our static analysis is exponential in the number of possible concurrency states. For the worst case, assume every node of a flow graph can occur in the same concurrency state with every node from the other processes' flow graphs. If we let $T$ be the number of nodes of all the processes' flow graphs, then an upper bound on the number of nodes of one flow graph is $O(T)$. The worst case bound on the number of concurrency states is $O(T^N)$, where $N$ is the number of processes in the distributed application.

Although static analysis can have exponential performance, the time spent analyzing does not affect the execution of the distributed system. The analysis is done prior to execution, and provides insight into the application's behavior.

Performance improving refinements to the analysis algorithms have been considered. Localized portions of the POG can be constructed based on the location of the assert statement. Only the events that occur before the execution of the assert statement need to be represented in the POG. Representation of communication events that occur after the last $LCP'$ events is not necessary to determine the remaining $LCP$ and $LCP'$ events. Our algorithms can be modified to determine the last $LCP'$ events before constructing $H$ and
CHAPTER 9. CONCLUSIONS

POG graphs. When a last \( LCP' \) event is represented in \( H \), construction of that branch of execution can stop. This can result in a smaller \( H \) and POG, depending on the location of the assert statement.

Space conservation is possible by not generating the complete \( H \) graph prior to generating the POG. As a portion of the \( H \) graph is generated, the corresponding portion of the POG can be generated. This portion of \( H \) is no longer needed and can be discarded. The space required to store the entire \( H \) graph would not be necessary.

9.3 Future Work

Our work can be extended in several directions. Three major areas are described.

9.3.1 Data Analysis

To minimize the amount of piggybacked data, we statically analyze a distributed program and identify the \( LCP \) and \( LCP' \) events. This can greatly reduce the number of messages piggybacking data. Additional reductions can be obtained by performing data analysis with regard to the assert statement. In the simplest case, processes only send state information regarding variables used in the asserted predicate. The amount of data piggybacked, and the sizes of the causal state buffers are reduced to include only relevant variables. The maximum size of a process's causal state buffer is one tuple for each variable in the assert. Since a process only piggybacks the contents of its causal state buffer, this maximum also applies to the increased size of messages.
Consider a distributed program where a process's \( LCP \) event is executed more than one time (e.g., it occurs in the body of a loop), as demonstrated in the distributed program SETPART where process \( P_0 \)'s \( LCP \) event occurs in a while loop. If \( P_0 \)'s state information changes every time the \( LCP \) event is executed, then this state information should be piggybacked to correctly propagate the state of the process. If, however, the state information does not change, piggybacking duplicate state information is not necessary.

Sophisticated static analysis, such as data flow analysis [1], can provide the information required to determine whether the state of the process has changed since the last piggybacking of state information. This type of static analysis, in combination with determining the \( LCP \) and \( LCP' \), can provide additional reductions in the amount of piggybacked data.

9.3.2 Modifications to the Distributed Program

If we change the location of an assert statement or add assert statements to the distributed application, the affects to our static analysis are minor. The \( POG \) does not require modification since a different assert location does not affect the concurrency and causal relationships of the distributed program. When an assert is added or relocated in process \( P_i \), \( P_i \)'s flow graph can be updated with the appropriate location of the assert node. As with all assert statements, algorithm \texttt{BoundAssert()} is called to determine the \textit{last} \( LCP' \) events, and algorithm \texttt{FindLCPs()} is called to determine the \( LCP \) and \( LCP' \) events of the assert statement.

If the assert's predicate is changed, this will only affect data analysis. Although we have not developed these algorithms, we suspect that additional variables will not invalidate the
prior data analysis. If variables are removed, the corresponding portion of the data analysis should also be removed.

If the distributed program is altered, the effects to the already existing flow graphs and POG are dependent on the type of changes. Changes to assignment statements will not affect the POG but may alter the data analysis. Additions or deletion of control constructs which do not alter communication events will not affect the POG. If control constructs are added or deleted that affect communication events, or if communication events are added or deleted, the POG is affected. The effects may be incremental, meaning that only a portion of the communication analysis requires reevaluation.

Since distributed assert statements are initially intended as a tool for debugging, altering the distributed program is expected. Incremental static analysis may provide a feasible and efficient solution for updating the flow graphs and the POG.

9.3.3 Global Assert Statement

We have demonstrated the usefulness of evaluating assert statements with causal global states, but distributed systems may remain which require their execution to be monitored with global states. In chapter 3, algorithms that capture global states of the distributed system’s execution, problems capturing global states, and the lack of meaningful predicate evaluation with these states were described. Two of our conclusions about global state reasoning were (1) the consideration of all global states of the system is required for a meaningful evaluation of the predicate, and (2) obtaining global states should not invalidate other global states. Our work can be extended by developing a meaningful run-time evaluation of
a global assert statement, i.e., evaluation against all consistent cuts that include the assert statement.

The POG is useful for evaluating a global assert statement. It provides the information needed to determine the consistent cuts of the distributed system's computation that include the assert statement. By examining a partial order of a distributed program, we can determine a lower and upper bound communication event in each process that define the region of execution that is concurrent to an assert statement. If $P_j$'s lower and upper bound events are $lower_j$ and $upper_j$, then all events in $P_j$ that happen between $lower_j$ and $upper_j$ are concurrent to the assert statement. A process's LCP message is the lower bound message of the process's concurrent region. The upper bounds can be determined from the POG by a similar method to LCP determination with node traversal occurring downward instead of upward. Once the lower and upper bounds are found in each process, all valid consistent cuts of the assert can be constructed from the concurrent regions' events.

A run-time method of gathering the information of the consistent cuts is required for global assert statement evaluation. One possibility is to send each local state and corresponding vector time that results from the execution of an event concurrent to the assert to a monitor process. The monitor process can glue together, using vector time stamps, the received local states to form global states for assert statement evaluation. The monitor process will have all the state information necessary for a meaningful evaluation of the assert statement. An evaluation method based on gathering state information concurrent to the assert is meaningful since evaluation is done with all global states that result from a consistent cut including the assert statement.
Admittedly, this is only a starting point for developing a global evaluation method, but
the majority of the static analysis exists in the POG.

9.4 Concluding Remarks

A meaningful and reliable technique for examining the execution of distributed programs has
been our goal. By developing both causal distributed assert statements and a static analysis
technique for determining the \( LCP \) and \( LCP' \) events for piggybacking state information, we
have achieved our goal with minimal interference to the execution of a distributed program.
Existing run time debugging techniques are not reliable for detecting buggy programs since
they capture only one of many global states. The one captured global state may or may not
provide meaningful information. To capture a global state, these techniques add messages
to the distributed execution which alter the causal relationships among events.

Our results provide a practical tool for the distributed system engineer. As demonstrated
with our analyzed programs, the examination of an execution is easily achieved
by inserting assert statements that express the expected behavior of the program. Our
prototype evaluates the assert without requiring the programmer to alter the distributed
program or to log state information. The programmer will need to rethink his debugging
strategy. Instead of thinking globally, a causal view of the execution is necessary. Once this
is achieved, causal assert statements convey meaningful insight into the program’s behavior.
Appendix A

Grammar

The italicized variables are nonterminals, and the all capitalized nonterminals are tokens in the lexer. Terminals appear in monospaced font.

Asynchronous Library Functions
NAME

init_async - initialize the asynchronous message transmission facility

SYNOPSIS

#include <async.h>

int init_async(group, procid, numprocs, vtflag, simlost, nonfifo, traceflag)
    short group;
    short procid;
    short numprocs;
    short vtflag;
    double simlost;
    short nonfifo;
    short traceflag;

PARAMETERS

group
    a positive short integer identifying the process group to which this process is a member.

procid
    a short integer between 0 and numprocs-1 identifying the process number of this member of the process group.

numprocs
    a short integer indicating the number of processes in this process group.

vtflag
    a flag indicating whether or not vector clocks should be used during this execution. The difference in execution speeds and message sizes for most process groups is insignificant.

simlost
    a double floating point number representing the probability of messages sent from this process being lost during transmission. A value of 0.0 indicates that messages transmission is reliable and a value of 1.0 will cause all messages sent from this process to be lost.

nonfifo
    a flag indicating whether or not messages can be delivered out of order. Message order is simulated using the Miller-Park random number generator.

traceflag
    a flag indicating whether or not traces of the execution should be constructed. If traceflag is true, then a file named proguame.trace will be created. Refer to the async.h header file for the exact layout of the trace records.
DESCRIPTION

init_async initializes the asynchronous communication facilities provided by the libasync library. The first parameter identifies the group to which this process belongs. The group id is a short integer that identifies the set of processes within the distributed system. Processes are only allowed to communicate with other processes within their group. In addition, processes are only allowed to begin execution after all processes in the group have been started.

Each process in the system calls init_async to register with the process server and obtain the list of addresses for the other members of the group. Only after all members have registered are the processes allowed to proceed. If all processes have not registered within a specified timeout period, failure responses are sent to those processes that have registered and the group is removed from the registry. Later attempts to register within the same group are considered requests from a new group.

RETURN VALUES

0 Initialization failed. An indication of why should be printed to stderr.
1 Initialization was successful.

NOTES

The library containing this and other asynchronous communication related functions, along with the C header files are located in dennis/public. To use them with gcc, the following command should be used.

gcc source -Idennis/public/include -Ldennis/public/lib -lasync -lm -lIl

EXAMPLE PROGRAMS

Here are two programs that use asynchronous communication to send a simple "Hello World" string from process 0 to process 1. The receiving process then prints the number of bytes received and the received message. Notice that the message length is increased by 1 to insure the received message contains the '\0' string terminating character.

Process 0

```
#include <stdio.h>
#include <async.h>
main ()
```

```c
{  
    char message[32];  
    
    /* group: 101. process: P0. 2 processes in group */  
    init_async(101, 0, 2, 0, 0, 0);  

    sprintf(message,"Hello World");  
    /* send message to P1 */  
    async_send(1, message, strlen(message)+1);  

    /* finished */  
    close_async();  
}

Process 1

#include <stdio.h>
#include <async.h>
main ()
{
    char message[32];  
    int msglen:  
    
    /* group: 101. process: P1. 2 processes in group */  
    init_async(101, 1, 2, 0, 0, 0);  

    msglen = 32;  
    /* receive message from P0 */  
    async_recv(0, message, &msglen, 0);  
    printf("received %d bytes [%s]. msglen. message");  

    /* finished */  
    close_async();  
}

NAME

async_send - send an asynchronous message to another process

SYNOPSIS

#include <async.h>

int async_send( procid, msg, len )
   short procid;
   void *msg;
   int len;

PARAMETERS

procid a short integer between 0 and numprocs-1 identifying the target process in the process group. If -1 is given as the target process identifier, the message is broadcast to all other processes in the process group.

msg a pointer to the beginning address of a message to be sent.

len the length in bytes of the message. (Currently restricted to (MAXMSGSIZE) 10240 bytes.)

DESCRIPTION

If vector time is in use, the local component is incremented to indicate the occurrence of an event. The message pointed to by msg length len is then sent to process procid. If procid is -1, then the message is broadcast to all other processes in the process group. (See init_async(2) for a description of process groups.)

RETURN VALUES

0 The message was lost during the send process.

1 The message was successfully sent to the other process and awaits delivery.

NAME

async_recv - receive an asynchronous message from another process

SYNOPSIS

#include <async.h>

int async_recv( procid, msg, len, waitsecs )
    short procid;
    void *msg;
    int *len;
    int waitsecs;

PARAMETERS

procid    a short integer between 0 and numprocs-1 identifying the transmitting
          process in the process group. If -1 is given as the source process identi-
          fier, the message is accepted from and process in the process group.

msg       a pointer to the begining address of a message to be sent.

len       a pointer to an integer to contain the length of the message in bytes. It
          is initialized to the length of the message buffer. (Currently restricted
          to (MAXMSGSIZE) 10240 bytes.)

waitsecs  an integer number of seconds to wait for the arrival of a message. If
          no message has arrived within waitsecs seconds, the function returns a
          -1. A value of 0 indicates that the timer should not be used and the
          function will wait forever.

DESCRIPTION

If vector time is in use, the local component is incremented to indicate the occurrence
of an event. A message from process procid is copied to the address stored in msg. The
length of the message is stored in len. If procid is -1, then the message is
accepted from any process in the process group. (See init_async(2) for a description
of process groups.) This option will return the next message in the order of arrival.
If no message is available, the function will hang, waiting for an arrival. If no
message arrives within waitsecs seconds, then the function returns with a value of
-1.
RETURN VALUES

-1 No message was available for delivery within the time specified by the waitsecs parameter.

message length
The message was successfully received from the indicated process. Side effects are to store the message in the memory area pointed to by msg and to store the size of the received message in the integer pointed to by len.

NAME

close_async - terminate the asynchronous message transmission facility

SYNOPSIS

#include <async.h>

int close_async()

DESCRIPTION

close_async terminates the asynchronous communication facilities initialized by a
 call to init_async. This function should always be called by the program using the
 async library. Failure to do so could leave zombie children wandering about.

RETURN VALUES

1 Termination was successful. Does not return until termination has been
 completed.

SEE ALSO

init_async(2), async_send(2), async_recv(2), recv_qinfo(2), inc_vtime(2),
get_vtime(2)
APPENDIX B. ASYNCHRONOUS LIBRARY FUNCTIONS

NAME

recv_qinfo - check the status of the asynchronous message wait queues

SYNOPSIS

#include <async.h>

int recv_qinfo( procid )
    short procid;

PARAMETERS

procid a short integer identifying the sending process from which messages should be checked. A value of -1 indicates that messages from all processes should be reported.

DESCRIPTION

recv_qinfo checks to see if any messages are waiting to be delivered to this process from process procid.

RETURN VALUES

0 No messages are waiting to be delivered from the indicated process.

1 Messages are waiting to be delivered from the indicated process.

NAME

inc_vtime - increment the local component of the vector clock

SYNOPSIS

#include <async.h>

int inc_vtime()

DESCRIPTION

If vector clocks are being used in the asynchronous communication facilities, this function increments the local component to indicate the occurrence of a significant local event.

RETURN VALUES

0 Vector clocks are not being used in this execution. See init_async(2).

local vector clock component

The value of the local component of the vector clock is returned after it has been incremented to indicate success.

SEE ALSO

init_async(2). async_send(2). async_recv(2). close_async(2). recv_qinfo(2). get_vtime(2)
APPENDIX B. ASYNCHRONOUS LIBRARY FUNCTIONS

NAME

get_vtime - return the current vector clock values

SYNOPSIS

#include <async.h>

int get_vtime( vt )
    unsigned int *vt;

PARAMETERS

vt a pointer to an array of unsigned integers where the values in the vector
clock should be placed.

DESCRIPTION

If vector clocks are being used in the asynchronous communication facilities, this
function stores the current value of the vector clock in the array of unsigned integers
pointed to by vt.

RETURN VALUES

-1 An error has occurred preventing the completion of the operation.

 0 Vector clocks are not being used in this execution. See init_async(2).

 1 The current values of the vector clock have been successfully placed in
    the vt array.

SEE ALSO

inc_vtime(2)
APPENDIX B. ASYNCHRONOUS LIBRARY FUNCTIONS

NAME

trace - Add a local event record to a process' trace file

SYNOPSIS

#include <async.h>

int trace()

DESCRIPTION

trace is used with the asynchronous communication library event tracing facility. It creates an event record of type TRACE_LOCAL with the current vector time and adds that record to the trace information. See init_async(2) for information on initializing the tracing facilities.

RETURN VALUES

none No values are returned from this function.

SEE ALSO
